Abstract. Absorption, translocation, and metabolism of foliar-applied 14C-labeled sethoxydim (14C-sethoxydim) in sethoxydim-tolerant centipedegrass [Eremochloa ophiuroides (Munro) Hack.] and sethoxydim-sensitive goosegrass [Eleusine indica (L.) Gaertn.] were determined. The distribution of 14C in treated leaves indicated that similar amounts (≈ 3%) were found in the epicuticular wax fraction (chloroform wash) of both species after 6 hours. After 2 hours, 16% of the applied 14C-sethoxydim was absorbed in the treated leaf by centipedegrass, but only 2% was absorbed by goosegrass. After 2 hours, centipedegrass also readily translocated greater amounts of 14C than goosegrass (4.3% vs. 0.4%). Six hours after treatment, however, no differences were found in amounts absorbed by the treated leaf and translocated to apical and basal leaves. Because sethoxydim-tolerant centipedegrass absorbed and translocated similar amounts of 14C compared to the sethoxydim-sensitive goosegrass, these two mechanisms do not appear to be a means of tolerance. The major difference found between the two species was in the metabolism of sethoxydim. After 6 hours, 81% to 98% of the 14C in goosegrass extracts remained as 14C-sethoxydim. In contrast, only 1% of the 14C found in apical leaves, basal leaves, and roots of centipedegrass was identified as 14C-sethoxydim. These data indicated that differences in tolerance to sethoxydim between these two species were based on metabolism. Chemical name used: 2-[1-(ethoxyimino) butyl]-5-[2-(ethylthio)propyl]-3-hydroxy-2-cyclohexen-1-one (sethoxydim).

Sethoxydim is a foliarly applied, systemic herbicide that selectively controls monocotyledonous turf species (Chernicky et al., 1984; Hosaka et al., 1984). Tolerance to sethoxydim has been reported for some monocotyledonous turf species (Butler and Appleby, 1986; Hosaka et al., 1984; McCarty et al., 1986). Red fescue (Festuca rubra) and centipedegrass are tolerant to sethoxydim at amounts as high as 1.12 kg·ha−1 (Anderson and Coats, 1985; Butler and Appleby, 1986; Hosaka et al., 1984; McCarty et al., 1986; Wells and Constantin, 1985). Goosegrass control (≈ 90%) by sethoxydim at 0.44 kg·ha−1 has been observed (Chernicky et al., 1984). A question is therefore raised as to the basis of herbicide selectivity between the monocotyledons centipedegrass and goosegrass.

Penetration and translocation of 14C-sethoxydim have been evaluated in several crop species (Campbell and Penner, 1980; Hosaka and Takagi, 1987; Nalewaja and Skrzypczark, 1986; Rhodes and Coble, 1984; Swisher and Corbin, 1982; Wills, 1984). Translocation of 14C was similar in most species {oat (Avena sativa L.), sunflower (Helianthus annuus L.), linseed (Linum usitatissimum L.), soybean (Glycine max (L.) Merr.], johnsongrass [Sorghum halepense (L.) Pers.], pea (Pisum sativum L.) and goosegrass} with accumulation in regions of high metabolic activity. Rhodes and Coble (1984) found 14C-sethoxydim translocation to be both acropetal and basipetal.

Campbell and Penner (1985) examined the extent of sethoxydim metabolism in monocotyledonous and dicotyledonous plants. 14C-sethoxydim was rapidly metabolized by quackgrass [Agropyron repens (L.) Beauv.], barnyardgrass [Echinochloa crus-galli (L.) Beauv.], alfalfa [Medicago sativa L. ‘Saranac’], and navy bean [Phaseolus vulgaris L. ‘Seafarer’]. Ninety-eight percent of sethoxydim was metabolized after 24 hr in all species. Two metabolizes, previously shown to be phototoxic to barnyardgrass, contained the majority of 14C 24 hr after application (Campbell and Penner, 1980). They concluded that differences in metabolism of sethoxydim in treated leaves could not account for selectivity between susceptible monocots and tolerant dicotyledonous crop plants.

Sethoxydim’s mode of action is reported to involve plant membrane lipid alteration or modification (Hatzios, 1982). Burton et al. (1988), however, suggested that sethoxydim prevents fatty acid biosynthesis by inhibiting acetyl-coenzyme A carboxylase.

We have observed that centipedegrass is tolerant to sethoxydim, but information is lacking on the basis of selectivity between centipedegrass and goosegrass (McCarty et al., 1986). Therefore, research was conducted to examine absorption, translocation, and metabolism of 14C-sethoxydim in a sethoxydim-tolerant turfgrass species (centipedegrass) and a sethoxydim-sensitive weed species (goosegrass).

Materials and Methods

Centipedegrass was established from 2-cm-long stolons and goosegrass from seeds. Both grasses were placed in 1-liter styro-
of foam cups containing a 1 peat : 1 pearlite (v/v) amended potting medium. Grass plants were thinned to one plant per pot 3 weeks after establishment. Pots were watered once daily and fertilizer solution (15N–16P–17K) was added every other week until treatment. Plants were grown in a controlled environment with days/night at 30/24°C and 16-hr photoperiods. Light intensity was 400 µmol·s⁻¹·m⁻² and relative humidity ranged from 60% to 75%.

Uniformly ring-labeled ¹⁴C-sethoxydim (0.5 µCi/ml; 1 Ci = 37 GBq) was applied with a micropipette to the adaxial side of the second leaf of four-leaf-stage centipedegrass and third leaf of six-leaf-stage goosegrass. Radiolabeled sethoxydim (specific activity 13.06 µCi/µmol) was applied in a total volume of 10 µl. Oxysorbic [20 polyoxyethylene sorbitan monolaurate (POE)] surfactant was added at 0.1% (v/v) to the stock solution. Two and 6 hr following application, plants were harvested and roots washed with water to remove potting medium. Each plant was sectioned into four parts: treated leaf, shoots above treated leaf (apical leaves), shoots below treated leaf (basal leaves), and roots.

Absorption, penetration, and metabolism. Each treated leaf was placed in a glass bottle containing 20 ml of distilled H₂O and shaken for 1 min. An additional 10 ml of distilled H₂O was used to wash the leaves upon removal from the bottle. A 2-ml sample was then combined with ¹⁴CO₂-labeled absorbent cocktail solution (¹⁴CO₂, UNT-SORB, Research Products Intl., Mt. Prospect, Ill.) and assayed by liquid scintillation spectrometry (Packard Tri-Carb Model 3255, Packard Instrument, Downers Grove, Ill.) to quantitate unabsorbed sethoxydim. The treated leaf was then placed in a glass bottle containing 20 ml of chloroform and shaken for 1 min to extract any herbicide present in the leaf epicuticular wax. An additional 10 ml of chloroform was used to rinse the leaf upon removal. Chloroform extracts were evaporated to dryness in vacuo at 37°C. Methanol (30 ml) was added to the crystalline extract and a 2-ml sample taken for counting in liquid scintillation spectrometry. Quench corrections were obtained by the external standard method. Treated leaf and other sectioned plant parts were placed in separate glass bottles with 30 ml of methanol and homogenized for 1 min with an electric homogenizer. Bottles were washed with 5 ml of methanol and samples were homogenized for an additional 1 min. Samples were filtered through two layers of filter paper under vacuum and additional methanol added to obtain a total filtrate volume of 50 ml. A 2-ml sample was taken from filtrates and quantified by liquid scintillation spectrometry. Filtrates were then evaporated to dryness in vacuo at 37°C to concentrate radioactive forms. Methanol and chloroform, 0.5 ml of each, were added to the dry methanol extract precipitates to redissolve the radioactive forms in preparation for metabolite separation by thin-layer chromatography (TLC).

Silica gel TLC analytical plates (250 µm) (Whatman K61 Silica gel TLC plates) were used to separate ¹⁴C compounds in extracts. A 100-µl sample from each methanol extract was spotted 2 cm from the bottom of the TLC plates. Each plate was spotted with analytical grade sethoxydim for ultraviolet location of parent herbicide. TLC plates were developed in a 5 hexane : 1 acetone (v/v) solvent system to a 15-cm solvent front. A second solvent system, 65 chloroform : 25 methanol : 4 H₂O (by volume), was used independently from the hexane : acetone system to separate potential polar metabolizes from the origin.

Radioactive peaks and Rₖ values were located by scanning TLC plates with a radiochromatogram scanner (Bioscan System 400 Imaging Scanner, Washington, D.C.) and quantified by liquid scintillation spectrometry.

Data analysis. Treatments were arranged in a randomized complete block design with three replications. The experiment was repeated and data presented as an average over experiments. Results were adjusted to a common recovery rate of 100% for ease of presentation. Data were subjected to analysis of variance and plant part means were compared between species by least significant differences (LSD) at the 5% level.

Results and Discussion

Absorption and translocation. The bulk of ¹⁴C-sethoxydim remained on leaf surfaces of both grass species 2 and 6 hr after application (Table 1). However, the initial absorption of the ¹⁴C-sethoxydim in the treated leaf differed between centipedegrass and goosegrass (Table 1). Sixteen percent of applied radioactivity was recovered at 2 hr in the centipedegrass treated leaf, but only one-eighth as much in goosegrass, suggesting that less absorption occurred initially in goosegrass than in centipedegrass. After 6 hr, differences in absorption between species were not evident, indicating that, over time, differential absorption of sethoxydim does not occur in these two grass species. Our data are in agreement with the work of previous researchers, who reported large amounts of sethoxydim on leaf surfaces after 6 hr (Rhodes and Coble, 1984).

Amounts of ¹⁴C-sethoxydim translocates averaged ≈1.5% in centipedegrass apical leaves, basal leaves, and roots 2 hr after treatment, but 0.2% or less in goosegrass (Table 1). The extent of translocation 6 hr after treatment was similar for both species throughout all parts. Apparently, centipedegrass initially absorbed and translocated ¹⁴C-sethoxydim faster than goosegrass, but, after 6 hr, similar amounts were found in both grass species.

Metabolism. Three major ¹⁴C peaks were located by ultra-

| Plant species       | Water wash | Chloroform wash (epicuticular wax) | Treated leaf | Apical leaves | Basal leaves | Roots |

Data are the means of six observations.

Rf values for A, B, and parent sethoxydim peaks were 0, 0.57, and 0.84, respectively. Obtained by TLC in 65 chloroform : 25 methanol : 4 water (by volume).

violet light (254 nm) and by radiochromatogram scanning of TLC separations (Table 2). These peaks had Rf values of 0 (origin), 0.57, and 0.84 and are designated as peaks A, B, and parent sethoxydim, respectively. Peak A remained at or near the origin and is believed to be a polar conjugate of sethoxydim. Peak B is an unknown metabolite, while peak C co-chromatographed with parent sethoxydim.

The proportion of parent sethoxydim and its metabolites changed over time, with differences between centipedegrass and goosegrass being evident (Table 2). After 6 hr, 83% of the 14C in centipedegrass treated leaves was sethoxydim. However, in apical leaves, basal leaves, and roots only trace amounts (1%) of sethoxydim were observed. This result suggests that centipedegrass at least partially metabolizes or transforms the herbicide into nonphytotoxic forms(s). In contrast, after 6 hr, 81% to 98% of the 14C remained as unaltered sethoxydim in goosegrass apical leaves, basal leaves, and roots. Thus, tolerance of centipedegrass and sensitivity of goosegrass to sethoxydim can be explained in part by differences in metabolism of the herbicide between the two species.
