Walters

ABSTRACT

We report on SRG/eROSITA, ZTF, ASAS-SN, Las Cumbres, NEOWISE-R, and Swift XRT/UVOT observations of the unique ongoing event AT 2019avd, located in the nucleus of a previously inactive galaxy at $z = 0.029$. eROSITA first observed AT 2019avd on 2020-04-28 during its first all sky survey, when it was detected as an ultra-soft X-ray source ($kT ~ 85$ eV) that was $\geq 90$ times brighter in the 0.2 – 2 keV band than a previous 3σ upper flux detection limit (with no archival X-ray detection at this position). The ZTF optical light curve in the $\sim 450$ days preceding the eROSITA detection is double peaked, and the eROSITA detection coincides with the rise of the second peak. Follow-up optical spectroscopy shows the emergence of a Bowen fluorescence feature and high-ionisation coronal lines ([Fe x] 6375 Å, [Fe xiv] 5303 Å), along with persistent broad Balmer emission lines (FWHM~ 1400 km s$^{-1}$). Whilst the X-ray properties make AT 2019avd a promising tidal disruption event (TDE) candidate, the optical properties are atypical for optically selected TDEs. We discuss potential alternative origins that could explain the observed properties of AT 2019avd, such as a stellar binary TDE candidate, or a TDE involving a super massive black hole binary.

Key words. keyword 1 – keyword 2 – keyword 3

1. Introduction

Actively accreting supermassive black holes (SMBHs) have long been known to exhibit large amplitude flaring behaviour (e.g. Tohline & Osterbrock 1976; Antonucci & Cohen 1983; Penston & Pérez 1984; Shappee et al. 2014; Storchi-Bergmann et al. 2017; Frederick et al. 2019), whereby multi-epoch observations of galaxy nuclei, over year-long timescales, have revealed drastic changes in their luminosity. The physical mechanisms responsible for producing extreme accretion rate changes are still unclear, although various models have been suggested, such as state transitions in the inner disc (Noda & Done 2018; Ross et al. 2018), radiation pressure instabilities in the disc (Śniegowska &...
Czerny 2019), or tidal disruption events (TDEs; Merloni et al. 2015; Chan et al. 2019).

Whilst the sample of ignition events in galactic nuclei was previously limited to only a few objects, the advance of wide-field, high-cadence surveys over the last decade has facilitated the discovery of an increasing number of extreme state changes. This has resulted in tighter constraints on the timescales of flaring events for these systems. For example, Trakhtenbrot et al. (2019b) recently reported a new class of SMBH accretion event that sees a large amplitude rise in the optical/UV luminosity over timescales of months.

In addition to triggering drastic changes in the accretion rate in AGNs, TDEs can also cause quiescent black holes to transition into short-lived active phases. In a TDE, a star that passes too close to a BH is torn apart by strong tidal forces, with a fraction of the bound stellar debris then being accreted onto the BH (Hills 1975; Young et al. 1977; Gurtzadian & Ozermai 1981; Lacy et al. 1982; Rees 1988; Phinney 1989). Early TDE candidates were first identified through detection of large-amplitude (at least a factor of 20), ultra-soft X-ray flares (black-body temperatures between 40 and 100 eV) from quiescent galaxies during the ROSAT survey (Bade et al. 1996; Komossa & Bade 1999; Komossa & Greiner 1999; Greiner et al. 1999). Since then, the vast majority of TDE candidates have been optically selected, such as through the Sloan Digital Sky Survey (SDSS; e.g. van Velzen et al. 2011; Merloni, et al. 2015), the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS; e.g. Gezari et al. 2012; Holoien et al. 2019a), the Palomar Transient Factory (PTF; e.g. Arcavi et al. 2014), the Intermediate Palomar Transient Factory (iPTF; e.g. Blagorodnova et al. 2017; Hung et al. 2017), the All Sky Automated Survey for Supernovae (ASAS-SN; e.g. Holoien et al. 2014, 2016; Wevers et al. 2019; Holoien et al. 2019b), and the Zwicky Transient Facility (ZTF; e.g. van Velzen et al. 2019, 2020). Optically selected TDEs are characterised as blue nuclear transients with light curves showing longer/shorter rise and decay timescales relative to supernovae (SNe)/AGN, and a relatively smooth power-law decline. Optical spectroscopic follow-up of these events post-peak reveals blue continua (blackbody temperatures ~ 10^4K) with various broad emission lines (full width at half maximum, FWHM ≤ 10^4 km s^{-1}); a recent characterisation of the different TDE spectroscopic classes was presented by van Velzen et al. (2020). Although a number of TDE candidates have also been found through UV selection (GALEX, Gezari et al. 2008, 2009), and X-ray selection (XMM-Newton Slew, Esquej et al. 2007, 2008; Saxton et al. 2012, 2017), most of our understanding of TDEs is currently biased towards this set of observed properties of optically-selected TDEs.

Whilst most previous TDE searches focused on identifying TDEs in quiescent galaxies, an increasing number of candidates for TDEs in AGNs are being proposed in the literature (Merloni et al. 2015; Blanchard et al. 2017; Trakhtenbrot et al. 2019a; Liu et al. 2020; Ricci et al. 2020). In certain cases, the distinction between TDE and non-TDE-induced SMBH accretion state changes is becoming increasingly blurred (see also Neustadt et al. 2020). Variants of TDEs have also been proposed to explain more exotic phenomena, such as the recently observed quasi-periodic eruptions (QPEs) in a few galactic nuclei (Miniutti et al. 2019; Giustini et al. 2020; King 2020), and periodic flaring seen in an AGN (Payne et al. 2020). Other origins for extreme nuclear transients involve SNe in the AGN accretion disc (Rozyczka et al. 1995), or interaction of SMBH binaries (SMBHB) with an accretion disc (Kim et al. 2018). It is clear that such different physical origins may result in a diverse range of observed variability behaviours.

In this paper, we report on the ongoing extreme event AT 2019avd, which is a novel addition to the already diverse population of nuclear transients. AT 2019avd is associated to the previously inactive galaxy 2MASX J08233674+0423027 at z = 0.292 (see Fig. 1), and was first reported as ZTF19aaqtmgl at the Transient Name Server (TNS2) following its discovery by ZTF on 2019-02-09 UT1 (Nordin et al. 2019). The transient was independently detected more than a year later on 2020-04-28 as a new ultra-soft nuclear X-ray source (Malyali et al. 2020) during the first all-sky survey of the eROSITA instrument (Predehl et al., in press) on-board the Russian/German Spectrum-Roentgen-Gamma (SRG) mission.

This work presents X-ray (SRG/eROSITA, Swift/XRT), optical/UV/mid-infrared (MIR) photometric (ZTF, ASAS-SN, NEOWISE-R, Swift/UVOT), and optical spectroscopic (NOT/ALFOSC, Las Cumbres Floyds, ANU/WiFeS) observations of AT 2019avd. In Section 2, we report our X-ray observations and analysis of AT 2019avd, whilst the photometric evolution and host galaxy properties are presented in Section 3. We then present details of our optical spectroscopic follow-up campaign in Section 4, before discussing possible origins for AT 2019avd in Section 5, and conclude in Section 6. We adopt a flat $\Lambda\text{CDM}$ cosmology throughout this paper, with $H_0 = 67.7\, \text{km s}^{-1}\text{Mpc}^{-1}$, $\Omega_m = 0.309$ (Planck Collaboration XIII 2016); $z = 0.292$ thus corresponds to a luminosity distance of 130 Mpc. All magnitudes will be reported in the AB system, unless otherwise stated.

2. X-ray observations

2.1. eROSITA discovery

AT 2019avd was discovered in a dedicated search for candidate TDEs in the first eROSITA all-sky survey (eRASS1). Here, the eROSITA source catalogue (version 945 of the source detection pipeline of the eROSITA Science Analysis Software, eSASS,

\footnote{1 For large, well-defined AGN flares similar to those seen in Frederick et al. (2019), as opposed to stochastic AGN variability.}

\footnote{2 https://wis-tns.weizmann.ac.il/}

\footnote{3 all dates in this paper will be reported in UT format.}
Brunner et al. in prep.) was systematically examined for new soft X-ray sources associated with the nuclei of galaxies that showed no prior indication of being an AGN.

The eROSITA data for AT 2019avd are composed of four consecutive scans with gaps of 4 hr each and a mid-time of 2020-04-28. The total on-source exposure amounts to four consecutive scans with gaps of 4 hr each and a mid-date of 2020-04-28. The source was localised to (RA $\text{J2000}$ $\text{2020-04-28}$, Dec $\text{J2000}$ $\text{2020-04-28}$), with a 1σ positional uncertainty of 2″, which is consistent with the nucleus of the galaxy 2MASX J08233674-0423027.

Photons were extracted using the eSASS task SRCTOOL (version 945) choosing a circular aperture of radius 47″ (version 945) choosing a circular aperture of radius 36″ (version 945) choosing a circular aperture of radius 47″, with a 1σ positional uncertainty of 2″, which is consistent with the nucleus of the galaxy 2MASX J08233674-0423027.

No X-ray source has previously been detected at the location of AT 2019avd. Using both the Upper Limit Server4 and webPIMMS5, and assuming an absorbed black-body spectral model with $kT = 80$ eV, and Galactic neutral hydrogen column density (see also Section 2.3), $N_{H} = 2.42 \times 10^{20}$ cm$^{-2}$, we infer an 0.2 – 2 keV 3σ upper limit of $1.7 \times 10^{-14}$ erg cm$^{-2}$s$^{-1}$ for a serendipitous 7 ks XMM-Newton pointed observation obtained on 2015-04-08. Earlier constraints can be derived from ROSAT observations obtained on 1990-10-14, 1996-11-13, and 1997-04-11 with 3σ upper limits of $4.2 \times 10^{-13}$, $4.0 \times 10^{-13}$, and $1.2 \times 10^{-13}$ erg cm$^{-2}$s$^{-1}$, respectively.

eROSITA thus first observed AT 2019avd in a state where it had brightened by at least a factor of 90 in the 0.2 – 2 keV band relative to the deepest archival X-ray observation (luminosity history presented in Fig. 2).

2.2. Swift follow-up

Triggered by the eROSITA detection, a series of follow-up observations were performed with the Neil Gehrels Swift Obser-

| 2020-06-03 | 17.89 ± 0.04 | -   | -   |
| 2020-06-10 | 17.80 ± 0.04 | -   | -   |
| 2020-09-16 | 17.78 ± 0.05 | 18.17 ± 0.06 | 18.23 ± 0.05 |

8 At 2019avd, whilst a nearby circular region with 15″ radius aperture centred on the optical position of AT 2019avd, whilst a nearby circular region with 15″ radius was used for background subtraction. The photometry was extracted from each unique Swift observation ID, and is presented in Table 2 (we note that this photometry includes both AGN and host galaxy emission in order to be consistent with the SED fitting in Section 3.3). Relative to UV photometry obtained prior to the initial optical outburst (see Section 3.3 and Fig. 7), AT 2019avd has brightened by ∼ 1 mag in the UVW1, UVM2, and UVW2 bands, and brightens only by ∼ 0.1 – 0.2 mag over Swift observations between 2020-05-13 and 2020-09-16.
2.3. X-ray spectral fitting

X-ray spectra were analysed using the Bayesian X-ray Analysis software (BXA, Buchner et al. 2014), which connects the nested sampling algorithm MultiNest (Feroz & Hobson 2008) with the fitting environment CIAO/Sherpa (Freeman et al. 2001) and XSPEC (Arnaud 1996). The spectra were fitted unbinned using the C-statistic (Cash 1976), and the eROSITA and XRT backgrounds were both modelled using the principal component analysis (PCA) technique described in Simmonds et al. (2018). For each set of eROSITA and XRT spectra, a joint fit on both the source and background spectra was run. Two different models for the source spectra were used: (i) an absorbed black body (tbabs*blackbody), and (ii) an absorbed power law (tbabs*powerlaw). The equivalent Galactic neutral hydrogen column density, N\(_\text{H}\), was allowed to vary by 20% from its tabulated value in the HI4PI survey of 2.42 \(\times\) 10\(^{20}\) cm\(^{-2}\) (HI4PI Collaboration et al. 2016) during fitting. The complete set of priors adopted under each model is listed in Table 3, whilst an example of the BXA fit to the eROSITA spectrum is shown in Fig. 3, and spectral fit results are presented in Table 4.

Over the course of the six weeks following the initial eROSITA detection, there was no major variability in the 0.2 – 2 keV flux between the eROSITA and XRT observations (Table 4 and Fig. 4). However, the 0.2 – 2 keV flux in the last Swift epoch increased by a factor of about six relative to the previous observation.

AT 2019avd remained in an ultra-soft state during the Swift monitoring campaign, although there is variability in the inferred black-body temperatures (\(kT\) ranges between minimum and maximum values of 72 ± 8 eV and 132 ± 10 eV, respectively). The inferred black-body temperatures are similar to those measured in the X-ray emission of previously observed thermal TDEs (45 ≤ \(kT\) ≤ 130 eV, e.g. van Velzen et al. 2020), and are also consistent with the temperatures of the soft excess shown in AGN (e.g. Table A1 in Gliozzi & Williams 2020).

3. Photometric evolution and host galaxy properties

3.1. Optical evolution

The region around the position of AT 2019avd has been monitored by ZTF (Bellm et al. 2019; Graham et al. 2019) in the \(r\) and \(g\) bands from 2019-01-12 until the time of writing. On 2019-02-09 (over a year before the eROSITA detection), ZTF first detected the transient ZTF19aaiqmgl with an inferred separation from the galaxy centre of 0′′.04, and \(r\)-band magnitude 17.64 ± 0.07 (reference subtracted, Fig. 1).

For MJD<58855 (2020-01-07), we obtained a forced photometry ZTF light curve for AT 2019avd (Masci et al. 2019). For MJD>58855, we downloaded the ZTF light curve of AT 2019avd using the Lasair alert broker (Smith et al. 2019), which processes and reports to the community on transients detected within the large ZTF data streams. Both of these light curves are constructed from PSF-fit photometry measurements run on ZTF difference images. We also obtained additional photometric observations with the Spectral Energy Distribution Machine (SEDM; Blagorodnova et al. 2018) on the Palomar 60-inch telescope. The SEDM photometry was host-subtracted using SDSS reference images, as described in Fremling et al. (2016). These two light curves, and the host-subtracted SEDM photometry, were then combined for subsequent analysis, and are shown in Fig. 5.

After the initial detection on 2019-02-09, AT 2019avd continued to brighten until reaching its maximum observed brightness of \(r \sim 16.8\) mag on 2019-02-20. Between 2019-02-24 and 2020-01-01, the \(g\)-band magnitude of the host nucleus decayed nearly monotonically from 17.13±0.09 mag to 20.08±0.20 mag, followed by a re-brightening to 18.58±0.13 mag on 2020-05-03. The late time SEDM photometry around 2020-09-19 revealed a further brightening to \(r\) and \(g\)-band magnitudes of \(\sim 17.6\) mag and \(\sim 18.4\) mag respectively. The first eROSITA observation occurred during the rise of the second major peak of the ZTF light curve (Fig. 5).

The location of AT 2019avd has also been monitored in the \(V\)-band by ASAS-SN (Shappee et al. 2014; Kochanek et al. 2017) from February 2012 to November 2018, and in the \(g\)-band from October 2017 to September 2020 (the time of writing). No major optical outbursts were seen in the ASAS-SN light curve prior to the ZTF detection (Fig. B.1); given the joint ASAS-SN and ZTF light curves, it is likely that the system ‘ignited’ around MJD = 58510 (2019-01-27).

Table 3. Summary of priors adopted in the BXA analysis of the eROSITA and XRT spectra. For each fit, a log-uniform prior on $N_H$ between $(0.8 N_H, 1.2 N_H)$ was defined, where $N_H = 2.42 \times 10^{20}$ cm$^{-2}$ (see Section 2.3). $\Gamma$ denotes the slope of a power law, $kT$ the black-body temperature, $A$ the normalisation. The prior over $A$ is in units $1.05 \times 10^{-6}$ erg cm$^{-2}$s$^{-1}$.

| Model | Priors |
|-------|--------|
| $tbabs * blackbody$ | $log[kT / \text{keV}] \sim U(-2, 1)$, $log[A] \sim U(-10, 10)$ |
| $tbabs * powerlaw$ | $\Gamma \sim U(0, 8)$, $log[A] \sim U(-10, 10)$ |

Table 4. X-ray spectral fit results from applying BXA to the extracted eROSITA and XRT spectra, with uncertainties enclosing 68% of the posterior for each parameter. $F_{0.2-2\text{keV}}$ is the inferred observed (unabsorbed) flux under each model.

Fig. 5. NEOWISE-R (non-host subtracted, top) and ZTF/ SEDM (middle) light curves of AT 2019avd, with the immediate 0.2 – 2 keV X-ray history shown in the bottom panel. The eROSITA eRASS1 detection and the Swift observation from 2020-09-16 are the empty and filled black markers, respectively. The solid grey vertical line marks the MJD of the eRASS1 observation, whilst grey dashed lines mark the times of the NOT and the first FLOYDS spectrum (Table 5). No significant variability before the initial 2019 outburst is observed in the host nucleus of AT 2019avd with archival NEOWISE-R and ASAS-SN observations (Fig. B.1). The NEOWISE-R observations pre-outburst are observed with mean W1, W2 marked out in the top panel by the cream and orange dashed lines respectively. For plotting clarity, we omit the high-cadence ZTF Partnership observations obtained between MJD 58820 and 58860, and we rebin the ~ 3 SEDM observations in each filter into a single data point.
3.1.1. Rise and decay timescales in the light curve

In the following, we fit the light-curve model presented in equation 1 of van Velzen et al. (2019), which models the rise with a half-Gaussian function, and an exponential function for the decay, to the first and second peaks of the ZTF light curve, using UltraNest9 (Buchner 2016, 2019) as our sampler. While such a model is not physically motivated, it enables a comparison of the timescales involved in the light curve of AT 2019avd with those of the population of ZTF nuclear transients presented in van Velzen et al. (2019).

While fitting the first peak, we first filter out observations outside of the MJD period between 58450 and 58650, and we then run a joint fit of the g and r band observations in flux space. Our model has seven free parameters, defined following the notation of van Velzen et al. (2019): $\sigma_r$, $\sigma_g$, the rise timescale of the light curve in the r and g bands respectively; $\tau_r$ and $\tau_g$, the decay timescale of the light curve in r and g bands; $F_{\text{peak},r}$ and $F_{\text{peak},g}$, the peak flux in r and g bands; $t_{\text{peak}}$, the time of the peak of the light curve (to enable a comparison with van Velzen et al. 2019, we assume that the light-curve model peaks at the same time in both of these bands). For the second peak, we filter out observations outside of the MJD period 58840 and 59115 (the late-time SEDM datapoints are used in the fitting), and because we do not sample the decay of this peak, we only model the rise here. The model for the second peak has five free parameters, with $\tau_r$ and $\tau_g$ now being omitted. We list our priors in Table A.1, and present the fits in Fig. 6.

From the posterior means, we infer $\sigma_r = 7.9 \pm 0.3$, $\sigma_g = 7.2 \pm 0.2$, $\tau_r = 58.2 \pm 0.5$ and $\tau_g = 39.8 \pm 0.4$ days for the first optical peak (68% credible intervals). Whilst the rise timescales in each filter are consistent with each other to within 2$\sigma$, the decay timescales in each filter significantly differ. With $\tau_r > \tau_g$, the first peak shows a potential cooling signature during its decay phase, although we are unable to constrain the temperature evolution during this because of a lack of contemporaneous observations in other wavelength bands. Relative to the population of nuclear transients in van Velzen et al. (2019), one sees that these are short rise and decay timescales relative to those of AGN flares, and are thus more similar to those in the van Velzen et al. (2019) sample of TDEs and SNe (Fig. 6). As expected from Fig. 5, the inferred rise times for the second peak are longer and more AGN-like, with $\tau_r \sim 88$ days and $\tau_g \sim 93$ days.

3.2. Mid-infrared variability

The location of AT 2019avd was observed in the W1 (3.4 $\mu$m) and W2 (4.6 $\mu$m) bands by the Wide-Field Infrared Survey Explorer mission (WISE, Wright et al. 2010) in 2010, Near-Earth Object WISE (NEOWISE; Mainzer et al. 2011) in late 2010 and 2011, and from December 2013 until now, twice per year as part of the NEOWISE reactivation mission (NEOWISE-R; Mainzer et al. 2014). The NEOWISE-R light curve was obtained from the NASA/IPAC Infrared Science Archive10 by compiling all source detections within 5″ of the ZTF transient position. Individual flux measurements were rebinned to one data point per NEOWISE-R all-sky scan (using a weighted mean) and converted into magnitudes. The resulting light curve is shown in Fig 5.

The MIR light curve was observed to be flat prior to the initial ZTF outburst, but showed significant brightening in the first NEOWISE-R epoch obtained thereafter. Observations obtained ~6 months later found the source to still be in the bright state despite having faded by ~3 mag in the optical. The MIR brightening was also accompanied by a significant reddening, evolving from $W1 - W2 = 0.08$ mag in AllWISE, to a more AGN-like $W1 - W2 \sim 0.6$ mag during flaring. The $W1 - W2$ colour before the outburst is much lower than the suggested cuts ($W1 - W2 \gtrsim 0.7$ mag) for identifying AGNs in previous MIR classification schemes (Stern et al. 2012; Assef et al. 2013, 2018), further supporting the hypothesis that there was no strong recent AGN activity in AT 2019avd at that time (although the use of WISE colours for selecting AGNs is less effective at lower AGN luminosities; see discussion in Padovani et al. 2017).

3.3. Host-galaxy properties

The spectral energy distribution (SED) of the host galaxy of AT 2019avd was compiled from archival11 UV to MIR photometry from GALEX (FUV, NUV), SDSS DR12 (g, r, i, z), UKIDSS (y, J, H, K), and AllWISE (W1, W2). The SED was modelled using CIGALE (Burgarella et al. 2005; Boquien et al. 2019), which allows the estimation of the physical parameters of a galaxy by fitting composite stellar populations combined with recipes describing the star formation history and attenuation. The best-fitting model (see Fig. 7) is that of a galaxy with a stellar mass of $(1.6 \pm 0.8) \times 10^{10} M_\odot$, a star formation rate (SFR) of $0.17 \pm 0.05 M_\odot$ yr$^{-1}$, and little attenuation, $E(B-V) = 0.03 \pm 0.02$ mag, which experienced a burst of star formation $3.7 \pm 0.2$ Gyr ago. The inferred stellar mass and SFR place the host galaxy of AT 2019avd in the ‘green valley’ between the star-forming main sequence and quenched elliptical galaxies (adopting the green valley definition presented in Law-Smith et al. 2017).

9 https://github.com/JohannesBuchner/UltraNest
10 https://irsa.ipac.caltech.edu/frontpage/
11 ‘Archival’ is defined here by photometry taken prior to the initial ZTF optical outburst.
The SED fit suggests that the host galaxy did not show strong signs of nuclear activity prior to the detection of AT 2019avd. This is further supported by the absence of a radio counterpart in the FIRST catalogue (Becker et al. 1995) within 30” of AT 2019avd, with a catalogue upper detection limit at this position of 0.96 mJy/beam\textsuperscript{12}.

4. Optical spectral analysis

4.1. Spectroscopic observations

On 2019-03-15, ~33 days after the first observed peak in the ZTF light curve, an optical spectrum of AT 2019avd was obtained by Gezari et al. (2020) with the Alhambra Faint Object Spectrograph and Camera (ALFOSC)\textsuperscript{13} on the 2.56 m Nordic Optical Telescope (NOT). The spectrum was obtained with a 1” wide slit, grism #4 (covering the wavelength region from 3650-9200 Å), and the slit was positioned along the parallactic angle at the beginning of the 1800s exposure. Reductions were performed in a standard way using mainly iraf based software, including bias corrections, flat fielding, wavelength calibration using HeNe arc lamps immediately after the target and flux calibrations using observations of a spectrophotometric standard star.

No further spectra were taken until after eROSITA had detected the large-amplitude soft-X-ray flare from AT 2019avd in late April 2020, which triggered a further five epochs of spectroscopy (dates listed in Table 5) using the FLOYDS spectrographs (Brown et al. 2013) mounted on the Las Cumbres Observatory 2m telescopes at Haleakala, Hawaii, and Siding Spring, Australia. Each spectrum was taken with a 3.6ks exposure, using the ‘red/blu’ grism and a slit width of 2”. The spectra were reduced using PyRAF tasks as described in Valenti et al. (2014).

FLOYDS covers the entire 3500-10000 Å range in a single exposure by capturing two spectral orders (one red and one blue) simultaneously, yielding \( R \approx 400 \). The different orders are usually merged into a single spectrum using the region between 4900 and 5700 Å, which is present in both the red and blue orders. However, in this case, in order to avoid erroneous wavelength shifts at the blue edge of the red order (where there are fewer arcsines), all FLOYDS spectra were merged using a reduced stitching region of 5400 to 5500 Å\textsuperscript{14}. This stitching was done manually in Python, by replacing fluxes in that wavelength range with other arcsines, whilst the asymmetry of the H\( \gamma \) line is likely due to blending of H\( \beta \) and narrow [N\( ii \)] 6549, 6583 Å lines, whilst the asymmetry of the H\( \beta \) line is likely due to blending of H\( \gamma \) and [O\( iii \)] 4363 Å emission. The other notable features are the [S\( ii \)] doublet at 6717 and 6731 Å (again blended, but later resolved in the WiFeS spectrum), and the weak H\( e \) I emission at 5876 Å. As no archival spectrum of the host galaxy is available, we are unable to judge whether or not the main observed emission features appeared at the onset of the extreme optical variability.

The WiFeS spectrum from 2020-05-29 (Fig. 8) shows the same emission features as the NOT spectrum, with the addition of a broad emission feature around 4680 Å and an apparent increase in intensity of a set of high-ionisation coronal lines ([Fe\( xiv \)] 5303 Å and [Fe\( x \)] 6375 Å, with ionisation potentials of 392 and 262eV respectively). We assume that the [Fe\( x \)] is not blended with the [O\( i \)] 6364 Å emission feature, because the latter is expected to be a third of the intensity of the [O\( i \)] 6300 Å emission (e.g. Pelat et al. 1987), which is not detected.

The FLOYDS spectra (Fig. 8) show no major evolution in the Balmer emission line profiles, and show the broad emission feature around 4680 Å from 2020-05-10 (for epochs with sufficiently high S/N ratios in the blue wavelength range), which was reported to the TNS (and first identified in Trakhtenbrot et al. 2020).

4.3. Optical spectrum modelling

For the two higher resolution spectra (NOT and WiFeS), the region around the main observed emission lines is fitted separately (H\( \gamma \), 4240Å < \( \lambda < 44400 \) Å; He\( \text{II} \), 4500Å < \( \lambda < 48000 \) Å; H\( \beta \), 4700Å < \( \lambda < 50000 \) Å; H\( \alpha \), 6364Å < \( \lambda < 6764 \) Å; [S\( ii \)] doublet, 6650Å < \( \lambda < 6800 \) Å; and \( \pm 100 \) Å of the line centre for [O\( iii \)] 5007 Å, [Fe\( x \)] 6375 Å). Each emission line complex is modelled with multiple Gaussians (an overview of these is presented in Table A.2), and each complex is fitted independently of the others. For all spectral fits, we assume a flat continuum component during the fitting process, and run our model fitting using the region slice sampler option within UltraNest. Spectral fits for the NOT and WiFeS spectra are shown in Figs. 10 and 11, whilst the spectral fit results are listed in Tables 6, 7, and 8.

| UT Date     | Tel.  | Instrument | Exp. [ks] | Airmass |
|-------------|-------|------------|-----------|---------|
| 2019-03-15  | NOT   | ALFOSC     | 1.8       | 1.5     |
| 2020-05-10  | FTS   | FLOYDS-S   | 3.6       | 1.4     |
| 2020-05-12  | FTS   | FLOYDS-S   | 3.6       | 1.6     |
| 2020-05-18  | FTN   | FLOYDS-N   | 3.6       | 1.6     |
| 2020-05-29  | ANU   | WiFeS      | 1.8       | 1.5     |
| 2020-05-31  | FTS   | FLOYDS-S   | 3.6       | 1.7     |
| 2020-06-06  | FTS   | FLOYDS-S   | 3.6       | 1.9     |

AT 2019avd is presented in Table 5. We note that we have not found any archival optical spectra of the host galaxy that were obtained prior to the initial 2019 outburst discovered by ZTF.
4. Emission line diagnostics

4.4. Balmer emission

From the best-fitting spectral models, we infer a broad Balmer decrement, \( \frac{F(\text{H}\beta)}{F(\text{H}\beta)} \), of 3.4 in the WiFeS spectrum (we use superscripts ‘b’ and ‘n’ to refer to the broad and narrow components of a given emission line when such are clearly detected). Such a decrement is consistent with what is observed in AGNs (e.g. Dong et al. 2005, 2007; Baron et al. 2016), and is slightly higher than the predicted value of around 2.74-2.86\(^{15} \) for case B recombination (Baker & Menzel 1938) and thus a photoionisation origin. Whilst it was originally thought that the observed Balmer decrement above 2.86 may have been due to a mix of collisional excitation and dust reddening in the centre of the host galaxy, several papers have suggested that the fundamental driver for this variance is the reddening (e.g. Dong et al. 2007; Baron et al. 2016; Gaskell 2017). Dong et al. (2007) find that after accounting for reddening, the intrinsic distribution in the Balmer decrements above 2.86 may have been consistent with a case B recombination. Using these results, and by working on the assumption that the intrinsic Balmer decrement is set by Case B recombination to 2.86, we infer an \( E(B-V) \sim 0.17 \) and 0.65 mag from the observed distribution in the Balmer decrements above 2.86.

\(^{15} \) The predicted value is dependent on the assumed gas density and temperature.

Table 6. Emission line ratios relative to [O III] 5007Å, where the inferred [O III] 5007Å flux in each spectrum is \( 1.34 \pm 0.09 \times 10^{-15} \text{ erg cm}^{-2} \text{s}^{-1} \) and \( 4.8 \pm 0.7 \times 10^{-16} \text{ erg cm}^{-2} \text{s}^{-1} \). The two spectra were obtained with different slit widths and orientations, and have not been calibrated with independent photometric measurements, hence the line ratios relative to [O III] 5007Å reported here. A dashed entry indicates that a given emission line was not clearly detected in the optical spectral fitting.

| Date     | N II 4640 | He II 4686 | H\(\beta\) | H\(\alpha\) | [N II] (6549 + 6583) | [S II] (6716 + 6731) |
|----------|-----------|------------|-----------|------------|---------------------|---------------------|
| 2019-03-15 | -         | -          | 10\(^{+3}_{-2}\) | 38\(^{+3}_{-3}\) | 7\(^{+1}_{-1}\)       | 1.7\(^{+0.1}_{-0.1}\) |
| 2020-05-29 | 4\(^{+5}_{-3}\) | 6\(^{+7}_{-5}\) | 11\(^{+2}_{-5}\) | 41\(^{+5}_{-6}\) | 5\(^{+1}_{-1}\)       | 1.7\(^{+0.2}_{-0.2}\) |

Table 7. Emission line ratios from the WiFeS spectrum, where the narrow components were resolved. The superscript 'b' and 'n' denote the broad and narrow components, respectively.

| Line 1, Line 2 | F(Line 1)/F(Line 2) |
|----------------|---------------------|
| H\(\alpha\)^b, H\(\beta\)^b | 5.8 \pm 0.8        |
| H\(\alpha\)^n, H\(\beta\)^b | 3.4 \pm 0.1        |
| He II 4686, H\(\beta\)^b | 0.6 \pm 0.1        |
| N II 4640, H\(\beta\)^b | 0.4 \pm 0.1        |

\end{align*} \]
4.4.2. Bowen feature around 4680 Å

Both the FLOYDS and the WiFeS spectra show the emergence of a broad emission feature around 4680 Å, which is likely a blend of He II 4686 Å and N III 4640 Å. Although this feature overlaps with the 4400-4700 Å region, which can often show prominent Fe II emission in AGNs, we disfavour an Fe II origin here on the basis of no strong Fe II bump being observed from the strongest Fe II transitions in the 4500-4600 Å or ~5150-5350 Å ranges (e.g. Kovačević et al. 2010). When comparing the WiFeS AT 2019avd spectrum to the composite SDSS quasar spectrum presented in Fig. 2 of Trakhtenbrot et al. (2019b), which was constructed from about 1000 SDSS quasars with broad Balmer lines of FWHM ~ 2000 km s$^{-1}$, the He II emission in AT 2019avd is much stronger relative to the Balmer emission in the AGN composite.

The N III 4640 Å emission suggests the presence of Bowen fluorescence (Bowen 1928). He II Ly$\alpha$ photons at 303.783 Å are produced after recombination of He$^{++}$\textsuperscript{17}, and can then either escape, ionise neutral H or He, or, because of the wavelength coincidence of O III 303.799 Å and 303.693 Å, be absorbed by O III. If the latter happens, then the later decay of the excited O III can produce a cascade of emission lines escaping the region (e.g. 3047, 3133, 3312, 3341, 3444, and 3760 Å\textsuperscript{18}), and eventu-

\textsuperscript{16} Alternatively, the inferred $E(B - V)$ values are 0.10 and 0.59 if we assume that the intrinsic Balmer decrement is 3.06 as in Dong et al. (2007).

\textsuperscript{17} The He II ionisation potential is 54.4 eV.

\textsuperscript{18} Unfortunately, our spectra do not cover the 3000-4000 Å range to detect the other O III Bowen lines.
ally a FUV O \textsc{iii} 374.436 Å photon. The 374.436 Å can then be absorbed by ground-state N \textsc{iii}, which further triggers a cascade of emission lines (N \textsc{iii} 4100, 4640 Å). Bowen fluorescence typically requires a high flux of FUV/soft-X-ray photons in order to produce the He \textsc{n} Ly\textalpha photon.

We measure relative line intensities of $F(\text{He}\text{n})/F(\text{He}\text{b}) \sim 0.57$, $F(\text{N} \textsc{iii}4640)/F(\text{He}\text{n}) \sim 0.65$ and $F(\text{N} \textsc{iii}4640)/F(\text{He}\text{b}) \sim 0.37$. Netzer et al. (1985) predicted the relative Bowen line intensities in AGNs under a range of different metal gas densities and abundances, where they found that to produce the high $F(\text{He}\text{n})/F(\text{He}\text{b})$ ratios seen in AT 2019avd as well as the high observed $F(\text{N} \textsc{iii}4640)/F(\text{He}\text{b})$ ratio, the gas producing the Bowen fluorescence must have very high density ($n_\text{H} > 10^8 \text{cm}^{-3}$) and high N and O abundances relative to cosmic abundances.

4.4.3. Coronal lines

From the line fitting seen on the WiFeS spectrum in Fig. 11, we infer the luminosities of the [Fe \textsc{ii}] 6375 Å and [Fe \textsc{xiv}] 5303 Å emission lines to be $\sim 2 \times 10^{39}$ and $\sim 3 \times 10^{39} \text{erg s}^{-1}$. We also infer relative intensities of $F(\text{Fe} \textsc{ii} 6375)/F(\text{O} \textsc{iii} 5007) \sim 2.4$ and $F(\text{Fe} \textsc{xiv} 6375)/F(\text{O} \textsc{iii} 5007) \sim 3$. Based on the coronal line ratio definitions proposed in Wang et al. (2012), AT 2019avd is classified as an extreme coronal line emitter (ECLE), where extreme is defined relative to the line ratios seen in coronal line AGNs (e.g. Nagao et al. 2000) report a maximum line ratio for $F(\text{Fe} \textsc{ii} 6375)/F(\text{O} \textsc{iii} 5007)$ of 0.24 over a sample of 124 Seyferts). Also, given the non-detected set of [Fe \textsc{vii}] emission lines in AT 2019avd which are seen in some ECLEs, and relatively weak [O \textsc{iii}] 5007 Å emission, AT 2019avd belongs to the subset of ECLEs that were designated as TDEs in Wang et al. (2012).

The Fe coronal lines are narrower relative to the He \textsc{n} and N \textsc{iii} 4640 Å emission lines (Table 8), with FWHM for the [Fe \textsc{xiv}] 5303 Å and [Fe \textsc{ii}] 6375 Å of 1560 ± 140 and 770 ± 40 km s$^{-1}$ respectively. Under the assumption that the line widths are set by the virial motion of the gas, this suggests that the coronal lines are produced further away from the BH than the Bowen lines, and also with the higher ionisation coronal lines being produced closer to the BH than the lower ionisation lines. The width of [Fe \textsc{xiv}] 5303 Å is comparable to the observed Balmer emission. We also note the differing line profiles of the [Fe \textsc{xiv}] 5303 Å and [Fe \textsc{ii}] 6375 Å emission, with the latter showing a stronger blue asymmetry (Fig. 11).

As discussed in Wang et al. (2012), the weakness of [Fe \textsc{vii}] emission relative to [Fe \textsc{ii}] and [Fe \textsc{xiv}] may be explained through the coronal line gas either being overionised under a high X-ray flux, or due to collisional de-excitation of [Fe \textsc{vii}], because it has a lower critical density ($\sim 10^{10} \text{cm}^{-3}$) compared with the higher ionisation lines ($\sim 10^{13} \text{cm}^{-3}$, Korista & Ferland 1989).

4.4.4. Black hole mass estimate

We assume that the gas that produces the broad H\textbeta emission is virialised around the SMBH at the centre of the galaxy, and use the ‘single epoch’ mass-estimation technique (e.g. Vestergaard & Peterson 2006) to infer the black hole mass using the following scaling relation from Assef et al. (2011):

$$\log \left( \frac{M_{\text{BH}}}{M_\odot} \right) = A + B \log \left( \frac{L_\lambda}{10^{44} \text{erg s}^{-1}} \right) + C \log \left( \frac{\text{FWHM}}{\text{km s}^{-1}} \right),$$

with $A = 0.895$, $B = 0.52$ and $C = 2$. From the measured FWHM of the broad H\textbeta component 1420 km s$^{-1}$ and $L_{5100} = \lambda L_\lambda(5000\text{Å}) \sim 2 \times 10^{42} \text{erg s}^{-1}$ from the WiFeS spectrum	extsuperscript{19}, we then infer $\log(M_{\text{BH}}/M_\odot) \sim 6.3$, albeit with a large uncertainty of $\sim 0.3$ dex (Assef et al. 2011). We note that using this technique requires the correlations between continuum luminosity and radius of the broad line region (BLR, e.g. Kaspi et al. 2005) obtained in previous AGN reverberation mapping experiments to also hold for the BLR around the SMBH in AT 2019avd.

4.4.5. Baldwin, Phillips, and Terlevich line diagnostic

From the fitting of the WiFeS spectrum, we infer line flux ratios of $\log([\text{N} \textsc{ii}]/[\text{H}\text{a}]) = -0.099^{+0.015}_{-0.016}$ and $\log([\text{O} \textsc{iii}]/[\text{H}\text{b}]) = 0.09^{+0.08}_{-0.10}$. According to a Baldwin, Phillips, and Terlevich (BPT) line diagnostic test (Baldwin et al. 1981), such line ratios suggest that a blend of star formation and AGN activity is responsible for producing the narrow line emission in the host galaxy of AT 2019avd (Kaufrmann et al. 2003; Kewley et al. 2006). Without an archival spectrum though, it is unclear whether the [O \textsc{iii}] 5007 Å and [N \textsc{ii}] 6583 Å lines have increased in intensity since the initial ZTF outburst, or an AGN-like ionising source has always been present.

\textsuperscript{19} $L_{\lambda}(5100\text{Å})$ is computed from the mean of $L_\text{b}$ between 5095 and 5105 Å.
4.5. Mapping out the BLR

Assuming that each observed emission line is broadened due to its virial motion around the central BH, we can use the measured FWHMs to obtain rough estimates of the distances from the central ionising source at which each line is produced (Fig. 12). Similar to previous work (e.g. Korista et al. 1995; Kollatschny 2003; Bentz et al. 2010), we also find evidence for a stratified BLR, whereby the higher ionisation lines are produced in regions closer to the BH.

5. Discussion

Based purely on its X-ray luminosity evolution, AT 2019avd most likely involves an accreting SMBH at the centre of a galaxy. Whilst the large amplitude X-ray flaring (factor of $\gtrsim 600$), soft X-ray spectrum, lack of previous strong (and sustained) AGN activity, and the implied unabsorbed X-ray peak luminosity in the $0.2 - 2$ keV energy range of $2 \times 10^{38}$ erg s$^{-1}$ (using spectroscopic $z = 0.029$, see section 4.1) initially made the source a strong TDE candidate, this is clearly discordant with the double-peaked optical variability seen in the ZTF observations (it does not look like a prototypical, single-event TDE as observed elsewhere). In the following section, we discuss potential origins of the rich phenomenology seen in AT 2019avd.

5.1. AT 2019avd as non-TDE-induced AGN variability

If AT 2019avd is related to AGN activity that was not induced by a TDE (herein referred to simply as AGN ‘activity’ or ‘variability’), then the combination of its X-ray and optical light curves make it one of the most extreme cases of AGN variability observed to date.

It is clear that the X-ray spectrum of AT 2019avd (section 2.3) is far softer than what is commonly seen in Seyfert 1s; for example, the power-law slope for Swift OBSID 00013495001 was $5.3^{+0.6}_{-0.5}$, whilst Nandra & Pounds (1994) model the observed power-law slope distribution with a Gaussian distribution of mean 1.95 and standard deviation 0.15. However, based on the measured FWHMs of the broad Balmer emission lines in the optical spectrum, it would be classified as a NLSy1, and softer spectral indices have also been observed in the NLSy1 population; a systematic ROSAT study of this by Boller et al. (1996) found power-law slopes of up to $\sim 5$. NLSy1s are also known to exhibit rapid, large-amplitude X-ray variability (e.g. Boller et al. 1996). As the X-ray variability of NLSy1s over longer timescales has not been extensively monitored before, how common AT 2019avd-like X-ray flares are within this population is currently unclear. For this reason, the X-ray properties alone cannot be used to state that the observed variability in AT 2019avd was induced by a TDE.

However, AT 2019avd shows a number of features in its optical spectrum that are infrequently seen in NLSy1s. First, NLSy1s commonly show strong Fe $\alpha$ emission (e.g. Rakshit et al. 2017), whereas this is not seen in the WiFeS spectrum, and only a weak Fe $\alpha$ complex is seen in the NOT spectrum in AT 2019avd. Instead, the most prominent Fe emission we observe are the transient, ECLE-like higher ionisation coronal...
lines of [Fe xiv] 5303 Å and [Fe x] 6375 Å in the WiFeS spectrum. During our spectroscopic follow-up campaign, we also observe the appearance of Hα 4686 Å and N ii 4640 Å emission lines (attributed to Bowen fluorescence). The optical spectrum at late times appears similar to the recently identified new class of flaring transients by Trakhtenbrot et al. (2019b), and we present a comparison of AT 2019avd with this class in Fig. 13. Whilst AT 2019avd shares the broad emission feature around 4680 Å with the AT 2017bgt flare class, the optical spectrum of AT 2019avd is distinguishable from the other members based on its much weaker [O iii] 5007 Å emission line. A likely reason for this is that the host galaxies of the other flares had persistent, higher luminosity AGNs in them prior to the optical outburst, relative to AT 2019avd. In addition, AT 2019avd’s large amplitude, ultra-soft X-ray flare, and its optical light-curve evolution make it unique amongst the AT 2017bgt flare class.

Finally, we stress that the double-peaked optical variability shown by AT 2019avd is unprecedented for a NLSy1, which when combined with its X-ray properties, make AT 2019avd clearly unique relative to all previous examples of AGN variability. Further examples of NLSy1 variability seen during the ZTF survey will be presented in a separate publication (Frederick et al. 2020).

5.2.2. Canonical tidal disruption event

As AT 2019avd shows a very-large-amplitude, soft-X-ray flare from the nucleus of a galaxy that shows no strong signs of prior AGN activity, it appears similar to the predicted observational signatures for TDEs (e.g. Rees 1988) and most of the previous X-ray-selected thermal TDE candidates (Bade et al. 1996; Komossa & Bade 1999; Komossa & Greiner 1999; Grupe & Leighly 1999; Greiner et al. 2000; Saxton et al. 2019). On the other hand, its optical spectrum shows a far weaker blue continuum component relative to that seen in optically selected TDEs, as well as narrower Balmer emission lines (for TDEs where these are detected); based on these two pieces of evidence, it would be straightforward to declare that AT 2019avd is not a TDE candidate, according to criteria for optical TDE selection in van Velzen et al. (2020).

The observed broad Balmer emission lines in AT 2019avd instead appear more like those commonly seen in the broad emission lines of Seyfert 1s. With such similarity, a mechanism analogous to the broad line emission in AGNs is likely operating
in AT 2019avd, whereby the line widths of hydrogen recombination lines are set by the gas kinematics (whereas some TDEs may have line widths set by repeated non-coherent electron scattering; e.g. Roth & Kasen 2018), and the high densities in the BLR result in the line intensity responding effectively instantaneously to changes in the continuum flux. In the limit of a weak TDE-like reprocessing layer\textsuperscript{21}, the optical spectrum of a TDE may appear similar to that of an AGN, as has been previously suggested (e.g. Gaskell & Rojas Lobos 2014). The timescales for the evolution of the spectral features in such systems may be different from those observed in optically selected TDEs, as they originate from a region further away from the BH than the reprocessing layer.

The optical emission mechanism in TDEs is currently not well understood, although it is thought to arise either from shocks produced from stellar debris stream self-intersections (Shiokawa et al. 2015; Piran et al. 2015), or from debris reprocessing the emission from an accretion disc (e.g. Loeb & Ulmer 1997; Ulmer et al. 1998; Roth et al. 2016; Roth & Kasen 2018). However, it is unclear how luminous the shocks are from stream self-intersections, whilst for the reprocessing scenario we still do not understand where the reprocessor is situated, where it forms, how large its covering angle would be from the BH, how efficiently it converts disc emission into the optical wavebands, or how all of these aspects are affected by the properties of the BH and those of the disrupted star. There is currently not a large enough sample of TDEs selected through both X-ray and optical surveys to test these various models of optical emission, and to properly assess the various complex underlying selection effects likely present in the existing TDE candidate population. A key example of these effects is the fact that only a small fraction of optically selected TDEs show transient X-ray emission (\sim 25% of optically selected TDEs in van Velzen et al. 2020 were X-ray bright); Dai et al. (2018) suggested that the observed properties of a TDE may be dependent upon the viewing angle to the newly formed disc.

Given the above, and that there are also no X-ray selected, non-relativistic TDEs in the literature that have high-cadence optical photometric light curves available\textsuperscript{22}, we cannot rule out a TDE-related origin for AT 2019avd simply on the basis of a lack of optically selected TDE features in the optical spectrum. However, we do disfavour the canonical TDE interpretation (seen in optically selected TDEs) for this flare on the basis of the double-peak optical light curve, which has not been observed in any of the TDEs identified by ZTF so far. Secondary maxima have previously been seen in the light curves of some TDE candidates (a compilation is presented in Fig. 8 of Wevers et al. 2019), though not at optical wavelengths and of far smaller amplitude increase compared with AT 2019avd (with the exception of the TDE in an AGN candidate in Merloni et al. 2015).

5.2.2. A more exotic variant of a tidal disruption event?

A large fraction of stars may exist in binary systems (e.g. Lada 2006). Mandel & Levin (2015) studied the various outcomes of a binary star passing close to a SMBH from a nearly radial orbit. In \sim 20% of such approaches, a double tidal disruption event (DTDE) is produced, whereby both stars in the binary are disrupted in succession. These latter authors estimated that \sim 10% of all stellar tidal disruptions could be associated with DTDEs, with such events expected to produce double-peak light curves.

We can use the inferred rise-to-peak timescales from the ZTF light curves to test the feasibility of whether AT 2019avd may have been triggered by a DTDE, specifically for the case where each peak is associated with the rise to peak mass fallback of each successive disruption. Guillochon & Ramirez-Ruiz (2013) present the time taken for a single TDE to reach peak mass fallback rate (in their equation A2):

\[
t_{\text{peak}} = B_{\text{f}} \left( \frac{M_{\text{BH}}}{10^6 M_\odot} \right)^{1/2} \left( \frac{M_\star}{M_\odot} \right)^{-1} \left( \frac{R_\star}{R_\odot} \right)^{3/2} \text{years},
\]

where \(B_{\text{f}}\) is a function of \(\beta\), the ratio of the tidal radius of the BH to the peri-centre of the orbit of the star, \(\gamma\) is the polytropic index of the star\textsuperscript{23}. \(M_{\text{BH}}\) is the black hole mass, and \(M_\star\) and \(R_\star\) are the mass and radius of the star being disrupted.

Similarly to Merloni et al. (2015), we then generate a grid of \(M_\star\) and \(\beta\), log-uniformly between (0.1\(M_\odot\), 100\(M_\odot\)) and (0.5, 4), respectively, and compute \(R_\star\) for each \(M_\star\) using the mass–radius relationship for zero-age main sequence stars presented in Tout et al. (1996). For each possible combination of \(M_\star\) and \(\beta\), and for a black hole with log\([M_{\text{BH}}/M_\odot]\) \sim 6.3, we check whether it can produce \(t_{\text{peak}}\) (using equation 2) within 20% of the observed peak timescales in the ZTF light curves (\sim 24 days and \sim 260 days for the first and second peak respectively). We also enforce the

\textsuperscript{21} And likely a lack of optically-selected observed TDE features.

\textsuperscript{22} Although the 4 X-ray bright TDEs in van Velzen et al. (2020) were monitored at a high cadence with ZTF and Swift UVOT, these were optically-selected TDEs.

\textsuperscript{23} We use \(\gamma = 4/3\) for \(0.3 M_\odot < M_\star < 22 M_\odot\), and \(\gamma = 5/3\) for \(M_\star\) outside this range, as in Mockler et al. 2019.
constraint that its tidal radius lies outside of the Schwarzschild radius for the system, so that it can produce a TDE with the star being swallowed whole by the black hole.

We plot the permitted regions of the $M_\ast$, $\beta$ parameter space in red in Fig. 14, where we see that no main sequence binary star configuration can reproduce the observed rise times for both the first and second peaks. It would also be possible to obtain further constraints on the feasibility of this scenario based on the observed peak luminosities (similar to Merloni et al. 2015) and their ratio, as well as from the inferred properties of the binary itself, such as from the time between the two observed peaks (which could be used to constrain the semi-major axis) and the inferred mass ratio. However, the constraints provided from $t_{\text{peak}}$ are perhaps the simplest to implement and are sufficient to highlight the caveats of a simple DTDE interpretation.

Bonnerot & Rossi (2019) recently suggested that following the disruption of a stellar binary, the two separate debris streams may collide prior to their fallback onto the black hole. These collisions then shock-heat the gas, and were predicted to produce an optical flare prior to the main flare of the disruption event. Such a model for a binary TDE could potentially explain the observed double-peak light curve, and the observed emergence of the Bowen feature after the second peak (the soft X-rays can only be emitted once the accretion disc has formed). However, a caveat to this interpretation is that the observed strong ionising flux and high gas densities are required for Bowen fluorescence to be produced, and we cannot confidently state here that the reason for not observing Bowen lines in the NOT spectrum is the absence of an X-ray-emitting accretion disc during that observation, because the absence of Bowen lines may also be due to insufficiently high gas densities (not all TDEs that are X-ray bright have displayed Bowen emission lines). We do not rule out this more complex DTDE scenario for AT 2019avd here, but do not perform a detailed comparison between the simulations in Bonnerot & Rossi (2019) and AT 2019avd in the present paper. Another alternative could be that AT 2019avd involved some type of TDE about a SMBH binary (e.g. Liu et al. 2009; Coughlin et al. 2017), where in such systems, the presence of the secondary BH can perturb the accretion flow onto the primary, leading to intermittent light curves.

5.3. Could AT 2019avd be supernova-related?

The spectra of Type IIn SNe can appear similar to those of AGNs (e.g. Filippenko 1989), as they can show broad and narrow emission lines, an absence of P-Cygni profiles, and higher luminosities and slower decay timescales relative to normal Type II SNe (Nyholm et al. 2020). Type IIn SNe typically also show the highest X-ray luminosities amongst all SNe. However, AT 2019avd has a $L_{0.2-2\text{keV}}$ that is about an order of magnitude higher than what is seen in most X-ray-luminous Type IIn SNe, when considering the sample of IIn shown in Fig. 3 of Dwarkadas & Gruszczo (2012). Furthermore, the X-ray emission from Type IIn SNe is predicted to be hard (e.g. Ofek et al. 2013), whilst that of AT 2019avd is ultra-soft. Based on the X-ray emission alone, we disfavour the idea that both optical peaks in AT 2019avd are related to a single Type IIn supernova.

Given the observed peak and decay timescales (Fig. 6), the peak absolute magnitude of the optical light curve ($\sim -18.5$), the small amount of reddening seen in the ZTF light curve during the decay phase, and the NOT spectrum, the first optical peak may have been associated with a Type IIn SN. The second optical peak would then be associated with a ‘turn on’ event in the SMBH that sees a vast increase in the accretion rate and the luminosity of the BH. This scenario would then explain why the He II, Bowen, and coronal lines are not seen in the NOT spectrum, and only in the spectra taken after the second peak. However, the probability of observing both a Type IIn SN and an AGN ‘turn on’ event within just over a year of each other is extremely small given the apparent rarity of extreme ‘turn-on’ events in AGNs (especially those showing an AT 2019avd-like X-ray outburst) and the expected detection rates for Type IIn SNe (e.g. Feindt et al. 2019), and we therefore disfavour a scenario where AT 2019avd is the chance coincidence of a Type IIn SN and extreme AGN ignition event within roughly one year of each other.

6. Conclusions

This paper presents an overview of a set of multi-wavelength observations of an exceptional nuclear transient, AT 2019avd, whose main observed features are as follows:

1. eROSITA detected an ultra-soft ($kT \sim 85$ eV) X-ray brightening ($\gtrsim 90$ times brighter than a previous $3\sigma$ upper flux limit) from a Previously X-ray-inactive galaxy (Section 2).
2. AT 2019avd was initially observed on a weekly basis with Swift XRT/UVOT for 6 weeks following the eROSITA detection. The host had brightened in all UVOT bands by $\sim 1$ mag relative to archival GALEX observations, and was observed with $0.2 - 2$ keV X-ray flux consistent with the eROSITA detection (Section 2). A further Swift observation ~5 months after the initial eROSITA detection revealed a brightening by a factor of approximately six in the $0.2 - 2$ keV band relative to the eROSITA detection. AT 2019avd therefore shows a net brightening in the $0.2 - 2$ keV band by a factor of at least 600 relative to the $3\sigma$ upper detection limit derived from an XMM-Newton pointing in 2015.
3. In the 450 days prior to the eROSITA detection, ZTF observed a double-peaked light curve (Section 3). The first optical peak shows rise and decay timescales akin to TDEs and SNe, whilst the rise time of the second peak is more similar to those seen in AGNs. No optical outbursts were detected.
during ASAS-SN observations over the seven years preceding the initial outburst seen by ZTF.
4. Optical spectroscopic follow-up finds transient HeI emission, Bowen fluorescence lines, and high-ionisation coronal lines ([Fe x] 6375 Å, [Fe xiv] 5303 Å) in the spectra taken after the second optical peak, but not in the spectrum taken 30 days after the first peak. The presence of such a set of lines requires an intense source of soft X-ray emission and extremely high densities. Broad Balmer emission lines were detected in spectra 30 days after the first peak in the ZTF light curve, as well as in all spectra taken in the weeks after the eROSITA detection with FWHM ~ 1400 km s$^{-1}$ (Section 4).

AT 2019avd thus shows a set of observed features which have never been observed together in the same nuclear transient before, and further complicates the non-trivial task of distinguishing the physical origin of large-amplitude variability seen in galactic nuclei. Whilst a discussion on the potential origins of this transient is presented in Section 5, it is still unclear what has triggered such exotic behaviour. Detailed simulations would be welcome to distinguish between the various possible scenarios. These will be well complimented with future planned observations (Swift, NICER, XMM-Newton) monitoring the late-time evolution of AT 2019avd. Finally, we note that during its eight successive all-sky surveys in the following years, eROSITA will successively monitor the X-ray variability of AGNs and map out the population of nuclear transients. With this information, we will better understand the extent of the X-ray variability shown by AT 2019avd, and make a more informed judgement on the origin of this transient.

Table A.2. Overview of the varying set of Gaussians used for modelling the emission lines in the NOT and WiFeS spectra.

| Region | Components |
|---|---|
| Hγ | Single Gaussian for each of Hγ and [O III] 4363 Å. |
| He II | Single Gaussian component for each of He II 4686 Å, and [N III] 4640 Å. |
| Hβ | Broad and narrow Gaussian component. |
| Hα | Broad and narrow Gaussian component for Hα, single Gaussian for each of [N II] 6549 and 6583 Å. |
| [S II] doublet | Single Gaussian for each of [S II] 6716 and 6731 Å. |
| [O III] 5007 Å, [Fe XIV] 5303 Å, [Fe X] 6375 Å | Single Gaussian for each. |
| 5007 Å, 5303 Å, 6375 Å | Single Gaussian for each. |

Appendix A: Optical spectrum and light-curve fitting

In Table A.1, we list the priors adopted in the fitting of the ZTF/SEDM light curves, whilst in Table A.2, we list the priors used in our fitting of the NOT and WiFeS optical spectra.

Appendix B: Long-term light curve of AT 2019avd

In Fig. B.1, we plot the long-term light curve of AT 2019avd, including the ASAS-SN data. ASAS-SN (Shappee et al. 2014) observed the location of AT 2019avd in V-band from February 2012 to November 2018 and in g-band from October 2017 to September 2020 (the time of writing). The V- and g-band observations were reduced using a fully automated pipeline detailed in Kochanek et al. (2017) based on the ISIS image subtraction package (Alard & Lupton 1998; Alard 2000). During each visit, ASAS-SN observed three 90-second dithered images that are then subtracted from a reference image. For the g-band we modified the standard pipeline and rebuilt the reference image without any images with JD ≥ 2 458 518 to prevent any flux contamination from the outbursts.

All subtractions were inspected manually to remove data with clouds, cirrus, or other issues. We note, however, that the ASAS-SN light curve was negatively affected by two factors. First, there is a bright nearby star that is not resolved from the host galaxy in ASAS-SN data and added noise to the subtractions. Second, the location of AT 2019avd is right on the edge of two ASAS-SN fields. To help alleviate these issues and increase the ASAS-SN limiting magnitude we stacked the subtractions within a maximum of 10 days. We then used the IRAF package apphot to perform aperture photometry with a two-pixel, or approximately 16.9′0, radius aperture on each subtracted image, generating a differential light curve. The photometry was calibrated using the AAVSO Photometric All-Sky Survey (Henden et al. 2015).
Fig. B.1. Long-term NEOWISE-R, ASAS-SN, and ZTF light curves of AT 2019avd. The early and late black dashed lines mark the 2015 XMM-Newton pointed and the 2020 eROSITA eRASS1 observations respectively. The early and late grey dashed lines mark the MJD that the NOT and first FLOYDS spectra were taken.
