ORDERS INDUCED BY SEGMENTS IN FLOORPLANS
AND (2-14-3, 3-41-2)-AVOIDING PERMUTATIONS

ANDREI ASINOWSKI, GILL BAREQUET, MIREILLE BOUSQUET-MÉLOU, TOUFIK MANSOUR,
AND RON Y. PINTER

Abstract. A floorplan is a tiling of a rectangle by rectangles. There are natural ways to order the elements—rectangles and segments—of a floorplan. Ackerman, Barequet and Pinter studied a pair of orders induced by neighborhood relations between rectangles, and obtained a natural bijection between these pairs and (2-41-3, 3-14-2)-avoiding permutations, also known as (reduced) Baxter permutations.

In the present paper, we first perform a similar study for a pair of orders induced by neighborhood relations between segments of a floorplan. We obtain a natural bijection between these pairs and another family of permutations, namely (2-14-3, 3-41-2)-avoiding permutations.

Then, we investigate relations between the two kinds of pairs of orders—and, correspondingly, between (2-41-3, 3-14-2)- and (2-14-3, 3-41-2)-avoiding permutations. In particular, we prove that the superposition of both permutations gives a complete Baxter permutation (originally called \(w\)-admissible by Baxter and Joichi in the sixties). In other words, (2-14-3, 3-41-2)-avoiding permutations are the hidden part of complete Baxter permutations. We enumerate these permutations. To our knowledge, the characterization of these permutations in terms of forbidden patterns and their enumeration are both new results.

Finally, we also study the special case of the so-called guillotine floorplans.

1. Introduction

A floorplan is a partition of a rectangle into interior-disjoint rectangles such that no point belongs to the boundary of four rectangles (Fig. 1). We call segment of the floorplan any straight line, not included in the boundary of the partitioned rectangle, that is the union of some rectangle sides, and is maximal for this property. For example, each of the floorplans of Fig. 1 has four horizontal and four vertical segments. Since four rectangles of a floorplan never meet, the segments do not cross, and a meeting of segments has one of the following forms: \(\rightarrow, \downarrow, \leftarrow, \uparrow\) (but not \(\uparrow\)).

![Figure 1. Two R-equivalent floorplans.](image)

An easy induction shows that the number of segments in a floorplan is smaller than the number of rectangles by 1. Throughout the paper, for a given floorplan \(P\), the number of segments in \(P\) is denoted by \(n\); accordingly,
$n + 1$ is the number of rectangles in $P$. We say that $P$ has size $n + 1$. For instance, the floorplans in Fig. 1 have size 9.

Many papers have appeared about floorplans, not only in combinatorics but also in the computational geometry literature [13, 25, 28]. The interest in floorplans is motivated, in particular, by the fact that their generation is a critical stage in integrated circuit layout [23, 24, 31, 37, 38], in architectural designs [8, 16, 19, 33, 34], etc.

The present paper is combinatorial in nature, and describes the relationship between a pair of natural orders defined on the segments of a floorplan and certain pattern avoiding permutations. It parallels a previous paper of Ackerman, Barequet and Pinter in which a similar study was carried out for a pair of orders defined on rectangles of a floorplan, in connection with the so-called Baxter permutations [1]. These permutations were introduced in the sixties, and were originally called reduced Baxter permutations, as opposed to complete Baxter permutations [6, 7, 11]. A complete Baxter permutation $\pi$ has an odd size, say $2n + 1$, and is completely determined by its values at odd points, $\pi(1), \pi(3), \ldots, \pi(2n+1)$. After normalization, these values give the associated reduced Baxter permutation $\pi_o$ (the subscript 'o' stands for odd; we denote by $\pi_e$ the permutation obtained by normalizing the list $\pi(2), \pi(4), \ldots, \pi(2n)$). Our paper provides the even part of the theory initiated in [1]: we prove that the permutation associated with the segments and the permutation associated with the rectangles are respectively the even and odd parts $\pi_e$ and $\pi_o$ of the same complete Baxter permutation $\pi$. We also characterize the even parts of Baxter permutations in terms of forbidden patterns and enumerate them.

This satisfactory final picture is, however, not our original motivation for studying segments of floorplans. Instead, our starting point was the observation that many questions on floorplans deal with segments rather than rectangles. An interesting example is the rectangulation conjecture [2, Conj. 7.1]. It asserts that for any floorplan $P$ of size $n + 1$, and any set $\Pi$ of $n$ points of the rectangle such that no two of them lie on the same horizontal or vertical line, there exists a floorplan $P'$, R-equivalent to $P$, such that each point of $\Pi$ lies on a segment of $P'$ (see Fig. 2 for an illustration). Such an embedding of points in segments of a floorplan is called a rectangulation. The rectangulation conjecture was suggested in connection with the minimization of the total length of segments in certain families of rectangulations [25]. Hence, the initial motivation of this paper was to provide us with a better combinatorial insight into problems related to floorplans and, in particular, to rectangulations.

![A floorplan P](image1.png) ![A point set \(\Pi\)](image2.png) ![\Pi embedded in \(P'\)](image3.png)

**Figure 2.** A rectangulation: embedding a point set $\Pi$ in a floorplan $P$.

In order to present our results in greater detail, we first need to describe the related results obtained for rectangles in [1]. In that paper, the authors study a representation of two order relations between rectangles in floorplans by means of permutations. These order relations are induced by neighborhood relations, which are defined as follows. A rectangle $A$ is a left-neighbor of $B$ (equivalently, $B$ is a right-neighbor of $A$) if there is a vertical segment in the floorplan that contains the right side of $A$ and the left side of $B$. (Note that the right side of $A$ and the left side of $B$ may be disjoint.) Now, the relation “$A$ is to the left of $B$” (equivalently,
“B is to the right of A”), denoted by $A \leftarrow B$, is defined as the transitive closure of the relation “A is a left-neighbor of B.” Finally, the relation $\leftrightarrow$ is the reflexive closure of $\leftarrow$. The terms $A$ is a below-neighbor of $B$ (equivalently, $B$ is an above-neighbor of $A$) and $A$ is below $B$ (equivalently, $B$ is above $A$) are defined similarly, as well as the notation $A \nshortdownarrow B$ for “$A$ is below $B$,” and $A \shortdownarrow B$ for “$A = B$ or $A \nshortdownarrow B$.” It is easy to see that the relations $\leftrightarrow$ and $\nshortdownarrow$ are partial orders. In both floorplans of Fig. 1, we have, among other relations, $A \nshortdownarrow I$ (because $A$ is a below-neighbor of $C$, and $C$ is a below-neighbor of $I$), $A \leftrightarrow G$, and $B \leftrightarrow F$.

The following results are proved in [1]. Let $P$ be a floorplan of size $n + 1$. Two distinct rectangles $A$ and $B$ of $P$ are in exactly one of the relations $A \nshortdownarrow B$, $B \nshortdownarrow A$, $A \nshortdownarrow B$, or $B \nshortdownarrow A$. It follows that the relations $\nshortdownarrow$ and $\nshortdownarrow$ between rectangles of $P$ defined by

$$A \nshortdownarrow B \iff A = B, \text{ or } A \nshortdownarrow B,$$

$$A \nshortdownarrow B \iff A = B, \text{ or } A \nshortdownarrow B,$$

are linear orders (the signs $\nshortdownarrow$ and $\nshortdownarrow$ are intended to resemble the inequality sign $\leq$). Each of these orders can be used to label the rectangles of $P$ by $1, 2, \ldots, n + 1$. In the $\nshortdownarrow$ order, the rectangle in the lower left corner is labeled 1, and the rectangle in the upper right corner $n + 1$. In the $\nshortdownarrow$ order, the rectangle in the upper left corner is labeled 1, and the rectangle in the lower right corner $n + 1$. Let $R(P)$ be the sequence $a_1 a_2 \ldots a_{n+1}$, where, for all $1 \leq i \leq n + 1$, $a_i$ is the label in the $\nshortdownarrow$ order of the rectangle which is labeled $i$ in the $\nshortdownarrow$ order. It is clear that $R(P)$ is a permutation of $[n + 1] := \{1, 2, \ldots, n + 1\}$; we call it the R-permutation of $P$. Loosely speaking, $R(P)$ is obtained by labeling the rectangles according to the $\nshortdownarrow$ order, and then reading these labels while passing the rectangles according to the $\nshortdownarrow$ order. Fig. 3 shows the construction of the R-permutation of a floorplan $P$; the right part of the figure is the graph of $\rho = R(P)$, that is, the point set $\{(i, \rho(i)) : 1 \leq i \leq n + 1\}$.

![Fig. 3. Constructing the R-permutation of a floorplan $P$.](image)

Two floorplans $P_1$ and $P_2$ of size $n + 1$ are said to be R-equivalent if there exists a labeling of the rectangles of $P_1$ by $A_1, A_2, \ldots, A_{n+1}$ and a labeling of the rectangles of $P_2$ by $B_1, B_2, \ldots, B_{n+1}$ such that for all $k, m \in [n + 1]$, the rectangles $A_k$ and $A_m$ exhibit the same neighborhood relation as $B_k$ and $B_m$. The two floorplans in Fig. 1 are R-equivalent: this follows from the labeling presented in this figure (in fact, $A, B, C, \ldots I$ is the $\nshortdownarrow$-order). It is easy to prove that two floorplans are R-equivalent if and only if they have the same R-permutation.

The main results of [1] state that for any floorplan $P$, its R-permutation is a $(241-3, 31-4-2)$-avoiding permutation, originally called (reduced) Baxter permutation; moreover, $R$ is a bijection between R-equivalence classes of floorplans and $(241-3, 31-4-2)$-avoiding permutations. Through this correspondence, the size of a

---

3Hence, $A \nshortdownarrow B$ should be understood as $A \nshortdownarrow B$; and similarly for $\nshortdownarrow$.

4In [1], two R-equivalent floorplans are actually treated as two representations of the same floorplan.

5This notation is explained in Section 3.3.
floorplan becomes the size of the permutation, and the order relations between rectangles in $P$ can be easily read from $R(P)$.

We can now describe our results in greater detail.

In the first part of the paper, we develop for segments a theory that parallels the theory developed for rectangles in [1]. We define two order relations between segments (Section 2), which leads to the notion of S-equivalent floorplans. Then we use these orders to construct a permutation $S(P)$ called the S-permutation of $P$. In Section 3 we prove that S-permutations coincide with (2-14-3, 3-41-2)-avoiding permutations, and that $S$, regarded as a function from S-equivalence classes to (2-14-3, 3-41-2)-avoiding permutations, is a bijection. The description of $S$ and $S^{-1}$ are fairly simple (both can be constructed in linear time), but as often, the proof remains technical, despite our efforts to write it carefully.

In the second part of the paper, we super-impose our theory with the analogous theory developed for rectangles in [1]. In Section 4 we show that R-equivalence of floorplans implies their S-equivalence (this means that the R-equivalence refines the S-equivalence), and explain how $S(P)$ can be constructed directly from $R(P)$. This construction shows that $S(P)$ and $R(P)$, combined together, form the so-called complete Baxter permutation associated with $R(P)$, as defined in the seminal papers on Baxter permutations [6, 7]. We also describe in terms of $R$ when two floorplans give rise to the same S-permutation. This is another difficult proof, but we need this description to express the number of (2-14-3, 3-41-2)-avoiding permutations in terms of the number of Baxter permutations (Section 5).

To finish, in Section 6 we characterize and enumerate S-permutations corresponding to the so-called guillo line floorplans; a similar study was carried out in [1] for R-permutations. We end in Section 7 with a few remarks.

2. Orders between segments of a floorplan

In this section we define neighborhood relations between segments of a floorplan, use them to define two partial orders (denoted $\rightarrow$ and $\downarrow$) and two linear orders (denoted $\nearrow$ and $\nwarrow$), and prove several facts about these orders. Most of them are analogous to facts about the orders on rectangles mentioned in the introduction, and proved in [1].

Definition 2.1. Let $P$ be a floorplan. Let $I$ and $J$ be two segments in $P$. We say that $I$ is a left-neighbor of $J$ (equivalently, $J$ is a right-neighbor of $I$) if one of the following holds:

- $I$ and $J$ are vertical, and there is exactly one rectangle $A$ in $P$ such that the left side of $A$ is contained in $I$ and the right side of $A$ is contained in $J$;
- $I$ is vertical, $J$ is horizontal, and the left endpoint of $J$ lies in $I$; or
- $I$ is horizontal, $J$ is vertical, and the right endpoint of $I$ lies in $J$.

The terms “$I$ is a below-neighbor of $J$” (equivalently, “$J$ is an above-neighbor of $I$”) are defined similarly.

Typical examples are shown in Fig. 4.

![Figure 4](image.png)

**Figure 4.** The segment $I$ is a left-neighbor of the segment $J$.

In the notion of R-equivalence and S-equivalence, $R$ stands for rectangles and $S$ for segments.
Note that a horizontal segment $I$ has at most one left-neighbor and at most one right-neighbor (no such neighbor(s) when the corresponding endpoint(s) of $I$ lie on the boundary), which are both vertical segments. In contrast, a vertical segment may have several left- and right-neighbors, which may be horizontal or vertical. This is illustrated in Fig. 5.

**Definition 2.2.** The relation “$I$ is to the left of $J$” (equivalently, $J$ is to the right of $I$), denoted by $I \leftarrow J$, is the transitive closure of the relation “$I$ is a left-neighbor of $J$.” The relation $\leftrightarrow$ is the reflexive closure of $\leftarrow$. The relations $I \downarrow J$ (“$I$ is below $J$”) and $I \nmid J$ (for “$I = J$ or $I \downarrow J$”) are defined similarly.

**Observation 2.3.** The relations $\leftrightarrow$ and $\downarrow$ are partial orders.

**Proof.** We prove the claim for the relation $\leftrightarrow$. Reflexivity and transitivity follow from the definition. For antisymmetry, note that $I \leftarrow J$ and $J \leftarrow I$ cannot hold simultaneously because if $I \leftarrow J$, then any interior point of $I$ has a smaller abscissa than any interior point of $J$. $\square$

The following observation may help to understand the $\leftrightarrow$ order. If $I$ and $J$ are vertical segments and right-left neighbors, let us create a horizontal edge, called *traversing edge*, in the rectangle $A$ that lies between them. Fig. 6 shows a chain of neighbors in the $\leftrightarrow$ order, starting from a vertical segment $I$, and the corresponding traversing edges (dashed lines).

**Observation 2.4.** Assume $I \leftrightarrow J$. Then any point of $J$ lies weakly to the right of any point of $I$ (that is, its abscissa is at least as large).

Let $x$ (respectively, $y$) be a point of minimal (respectively, maximal) abscissa on $I$ (respectively, $J$). Then there exists a polygonal line from $x$ to $y$ formed of vertical and horizontal sections, such that
It suffices to prove these properties when \( J \) is a right-neighbor of \( I \), and they are obvious in this case (see Fig. 4).

**Lemma 2.5.** In the \( \leftarrow \) order, \( J \) covers \( I \) if and only if \( J \) is a right-neighbor of \( I \). A similar statement holds for the \( \downarrow \) order.

**Proof.** Since \( \leftarrow \) is constructed as the transitive closure of the left-right neighborhood relation, every covering relation is a neighborhood relation.

Conversely, let us prove that any neighborhood relation is a covering relation. Equivalently, this means that the right-neighbors of any segment \( I \) form an antichain. If \( I \) is horizontal, it has at most one right-neighbor, and there is nothing to prove. Assume \( I \) is vertical (as in Fig. 5), and that two of its neighbors, \( J_1 \) and \( J_2 \), satisfy \( J_1 \leftarrow J_2 \). By the first part of Observation 2.4, \( J_2 \) cannot be horizontal (its leftmost point would then lie on \( I \), leaving no place for \( J_1 \)). Hence \( J_2 \) is vertical. The possible configurations of \( I \) and \( J_2 \) are depicted in the first four cases of Fig. 4. Let \( x \) (resp. \( y \)) be a point of \( I \) (resp. \( J_2 \)). By Observation 2.4 there exists a polygonal line from \( x \) to \( y \) that visits a point of \( J_1 \). This rules out the third and fourth cases of Fig. 4 (the line would be reduced to a single traversing edge). By symmetry we can assume that \( I \) and \( J_2 \) are as in the first case of Fig. 4. Then the polygonal line, which is not a single traversing edge, has to leave \( I \) at a point that lies lower than the lowest point of \( J_2 \), and to reach \( J_2 \) at a point that lies higher than the highest point of \( I \): this means that it crosses two horizontal segments, which is impossible given the description of this line. \( \square \)

**Lemma 2.6.** Let \( I \) and \( J \) be two different segments in a floorplan \( P \). Then exactly one of the relations: \( I \leftarrow J \), \( J \leftarrow I \), \( I \downarrow J \), or \( J \downarrow I \), holds.

**Proof.** Assume without loss of generality that \( I \) is a horizontal segment. Construct the \( \text{NE-sequence} \ K_1, K_2, \ldots \) of \( I \) as follows (see Fig. 7 for an illustration): \( K_1 \) is the right-neighbor of \( I \), \( K_2 \) the above-neighbor of \( K_1 \), \( K_3 \) the right-neighbor of \( K_2 \), and so on, until the boundary is reached. Construct similarly the \( \text{SE-}, \text{NW-}, \text{and SW-sequences} \) of \( I \). These sequences partition the rectangle into four regions (or fewer, if some endpoints of \( I \) lie on the boundary); each segment of \( P \) (except \( I \) and those belonging to either of the sequences) lies in exactly one of them. Also, if \( J \) is in the interior of a region, then its neighbors are either in the same region, or in one of the sequences that bound the region.

It is not hard to see that the vertical segments of the NE-sequence are to the right of \( I \), while horizontal segments are above \( I \). A horizontal segment \( K_{2i} \) cannot be to the left of \( I \), since it ends to the right of \( I \). Let us prove that \( K_{2i} \) cannot be the right of \( I \) either. Assume this is the case, and consider the polygonal line going from the leftmost point of \( I \) to the rightmost point of \( K_{2i} \), as described in Observation 2.3. The last section of this line is \( K_{2i} \). Hence the line has points in the interior of the region comprised between the NW- and NE-sequences. But since the line always goes to the right, and follows entirely every horizontal segment it visits, it can never enter the interior of this region. Thus \( K_{2i} \) cannot be to the right of \( I \). Thus, its only relation to \( I \) is \( I \downarrow K_{2i} \). Similar arguments apply for vertical segments of the NE-sequence, and for the other three sequences.

Consider now a segment \( J \) that lies, for instance, in the North region (that is the region bounded by the NE-sequence, the NW-sequence, and the boundary; the case of other regions is similar). Then \( I \) is below \( J \): if we consider the below-neighbors of \( J \), then their below-neighbors, and so on, then we necessarily reach one of the horizontal segments of the NW- or NE-sequence, which, as we have seen, are above \( I \) (we cannot reach a vertical segment of the sequences without reaching a horizontal segment first).

Hence, we have that \( I \downarrow J \); it remains to prove that the other three relations are impossible.
First, \( J \downarrow I \) is impossible since the relation \( \downarrow \) is antisymmetric. To prove that \( J \) cannot be to the right of \( I \), we argue as we did for \( K_2 \): the polygonal line from \( I \) to \( J \) starting from the leftmost point of \( I \) cannot enter the North region. Symmetrically, \( J \) cannot be to the left of \( I \). This completes the proof. \( \square \)

**Figure 7.** Four regions determining the relationship between \( I \) and other segments of the floorplan.

**Definition 2.7.** The relations \( \prec \) and \( \preceq \), between segments of a floorplan \( P \) are defined by:

\[
\begin{align*}
I \prec J & \quad \text{if} \quad I = J, \text{or} \ I \text{ is to the left of } J, \text{ or } I \text{ is below } J, \\
I \preceq J & \quad \text{if} \quad I = J, \text{ or } I \text{ is to the left of } J, \text{ or } I \text{ is above } J.
\end{align*}
\]

We also write \( I \prec J \) when \( I \not\prec J \) and \( I \not\approx J \); and \( I \preceq J \) when \( I \not\preceq J \) and \( I \not\approx J \).

**Proposition 2.8.** The relations \( \prec \) and \( \preceq \) are linear orders.

*Proof.* We prove the claim for the relation \( \prec \). Reflexivity follows from the definition. Antisymmetry follows from the fact that \( \prec \) and \( \downarrow \) are order relations, and from Lemma 2.6.

For transitivity, assume that \( I \not\prec J \) and \( J \not\prec K \). If \( I \prec J \) and \( J \prec K \) (respectively, \( I \downarrow J \) and \( J \downarrow K \)), then we have \( I \prec K \) (respectively, \( I \downarrow K \)) by the transitivity of \( \prec \) (respectively, \( \downarrow \)). Assume now that \( I \prec J \) and \( J \prec K \) (the case \( I \downarrow J \) and \( J \prec K \) is proven similarly). By Lemma 2.6, \( I = K \) is impossible, and we have either \( I \prec K \), \( K \prec I \), \( I \downarrow K \), or \( K \downarrow I \). However, the combination of \( K \prec I \) and \( I \prec J \) yields \( K \prec J \), contradicting the assumption that \( J \prec K \) (by Lemma 2.6). Similarly, combining \( K \downarrow I \) with \( J \downarrow K \) yields \( J \downarrow I \), contradicting the assumption that \( I \prec J \). Therefore, we have either \( I \prec K \) or \( I \downarrow K \); in particular, \( I \not\prec K \).

Linearity follows from Lemma 2.6. \( \square \)

**Observation 2.9.** The orders \( \prec \) and \( \downarrow \) can be recovered from \( \prec \) and \( \preceq \). Indeed, \( I \prec J \) if and only if \( I \not\preceq J \) and \( I \not\approx J \); moreover, \( I \downarrow J \) if and only if \( I \not\prec J \) and \( I \approx J \).

Throughout the paper, the \( i \)th segment in the \( \preceq \) order (\( 1 \leq i \leq n \)) will be denoted by \( I_i \). See Fig. 11 for examples.

We now explain how to determine \( I_{i+1} \) among the neighbors of \( I_i \). By Lemma 2.6, \( I_{i+1} \) is either a right- or below-neighbor of \( I_i \). There are several cases depending on the existence of these neighbors and the relations between them. For a horizontal segment \( I \), we denote by \( R(I) \) the right-neighbor of \( I \) (when it exists). By Lemma 2.5, the below-neighbors of \( I \) form an antichain of the \( \downarrow \) order. Since \( \preceq \) is a linear order, they are totally ordered for the \( \prec \) order. By the first part of Observation 2.4, the leftmost is also the smallest, denoted \( LB(I) \). Thus \( LB(I) \) is either \( LVB(I) \) (the leftmost vertical below-neighbor of \( I \)) or \( LHB(I) \) (the leftmost horizontal below-neighbor of \( I \)). Similarly, for a vertical segment \( I \), we denote by \( B(I) \) the below-neighbor of \( I \); by \( UR(I) \) the highest right-neighbor of \( I \), and by \( UHR(I) \) (respectively, \( UVR(I) \)) the highest horizontal.

\( ^7 \)The letter U stands for up.
(respectively, vertical) right-neighbor of \( I \). Fig. 8 illustrates the following observation (it is assumed that all candidates for \( I_{i+1} \) are depicted. The dashed lines belong to the boundary).

**Observation 2.10.** Let \( I_i \) be a segment in a floorplan \( P \) of size \( n+1 \). If \( I_i \) is horizontal, then \( I_{i+1} \) is either \( R(I_i) \) or \( LB(I_i) \). More precisely,

1. If none of \( R(I_i) \) and \( LB(I_i) \) exists, then \( I_i \) is the last segment in the \( \triangleright \) order (that is, \( i = n \)).
2. If exactly one of \( R(I_i) \) and \( LB(I_i) \) exists, then \( I_{i+1} \) is this segment.
3. If \( LVB(I_i) \) exists, then \( I_{i+1} = LB(I_i) \). This segment is \( LHB(I_i) \) if it exists, and otherwise \( LVB(I_i) \).
4. If \( LVB(I_i) \) does not exist but \( LHB(I_i) \) and \( R(I_i) \) exist, then
   - If the join of \( LHB(I_i) \) and \( R(I_i) \) is of type \( \flat \), then \( I_{i+1} = LHB(I_i) \).
   - If the join of \( LHB(I_i) \) and \( R(I_i) \) is of type \( \perp \), then \( I_{i+1} = R(I_i) \).

If \( I_i \) is vertical, then \( I_{i+1} \) is either \( B(I_i) \), \( UHR(I_i) \), or \( UVR(I_i) \) (the details are similar to those in the case of a horizontal segment).

**Proposition 2.11.** Let \( P \) be a floorplan of size \( n+1 \), and let \( A_k \) denote the rectangle labeled \( k \) in the \( \triangleright \) order. For \( 1 \leq k \leq n \), the following property, illustrated in Fig. 8 holds:

- If the segments forming the SE-corner of \( A_k \) have a \( \perp \) join, let \( J_k \) be the segment containing the right side of \( A_k \). Then \( A_{k+1} \) is the highest rectangle whose left side is contained in \( J_k \).
- If the segments forming the SE-corner of \( A_k \) have a \( \flat \) join, let \( J_k \) be the segment containing the lower side of \( A_k \). Then \( A_{k+1} \) is the leftmost rectangle whose upper side is contained in \( J_k \).

In both cases, \( J_k \) is the \( k \)th segment in the \( \triangleright \) order of segments, denoted so far by \( I_k \).

**Proof.** By definition of the \( \triangleright \) order, \( A_{k+1} \) is either a right-neighbor or a below-neighbor of \( A_k \). If there is a \( \perp \) join in the SE-corner of \( A_k \), then all the right-neighbors of \( A_k \) are above all its below-neighbors. Therefore, \( A_{k+1} \) is the topmost among them. If there is a \( \flat \) join in the SE-corner of \( A_k \), then all the below-neighbors of \( A_k \) are to the left of all its right-neighbors. Therefore, \( A_{k+1} \) is the leftmost among them.

To prove the second statement, we observe it directly for \( k = 1 \), and proceed by induction. One has to examine several cases, depending on whether the segments in the SE-corners of \( A_k \) and of \( A_{k+1} \) have \( \perp \) or \( \flat \) joins. In all cases, \( J_{k+1} \) is found to be the immediate successor of \( J_k \) in the \( \triangleright \) order, as described in Observation 2.10. See Fig. 10 for several typical situations.

The group of symmetries of the square acts on floorplans (when floorplans are drawn in a square). It is thus worth examining how the orders are transformed when applying such symmetries. As this symmetry group is generated by two generators, for instance the reflections in the first diagonal and across a horizontal line, it suffices to study these two transformations. The following proposition easily follows from the description of the neighborhood relations of Fig. 4.
Proposition 2.12. Let $P$ be a (square) floorplan, and let $P'$ be obtained by reflecting $P$ in the first diagonal. If $I$ is a segment of $P$, let $I'$ denote the corresponding segment of $P'$. Then

$$
I \leftarrow J \iff I' \not\leftarrow J',
I \downarrow J \iff I' \not\downarrow J',
I \not\twoheaddownarrow J \iff J' \not\twoheaddownarrow I',
I \not\twoheaduparrow J \iff I' \not\twoheaduparrow J'.
$$

If instead $P'$ is obtained by reflecting $P$ in a horizontal line,

$$
I \leftarrow J \iff I' \leftarrow J',
I \downarrow J \iff J' \downarrow I',
I \not\twoheaddownarrow J \iff I' \not\twoheaduparrow J',
I \not\twoheaduparrow J \iff J' \not\twoheaddownarrow I'.
$$

One consequence of this proposition is that a half-turn rotation of $P$ reverses all four orders. We shall also use the fact that, if $P'$ is obtained by applying a clockwise quarter-turn rotation to $P$, then $I \not\twoheaddownarrow J \iff J' \not\twoheaduparrow I'$.

3. A bijection between $S$-equivalence classes of floorplans and $(2\,14\,3,3\,41\,2)$-avoiding permutations

In this section we define $S$-equivalence of floorplans and construct a map $S$ from floorplans to permutations. We show that $S$ induces an injection from $S$-equivalence classes to permutations. We then characterize the class of permutations obtained from floorplans in terms of (generalized) patterns.

3.1. $S$-equivalence

Definition 3.1. Two floorplans $P_1$ and $P_2$ of size $n + 1$ are $S$-equivalent if it is possible to label the segments of $P_1$ by $I_1, I_2, \ldots, I_n$ and the segments of $P_2$ by $J_1, J_2, \ldots, J_n$ so that for all $k, m \in [n]$, the segments $I_k$ and $I_m$ exhibit the same neighborhood relation as $J_k$ and $J_m$. 
Fig. 11 shows two S-equivalent floorplans: in both cases, the left-right neighborhood relations are $1 \leftarrow 4$, $2 \leftarrow 4$, $3 \leftarrow 4$, $4 \leftarrow 5$, $4 \leftarrow 6$, and the below-above neighborhood relations are $2 \downarrow 1$, $3 \downarrow 2$, $6 \downarrow 5$. These floorplans are not R-equivalent, as can be seen by constructing their R-permutations. We will prove in Section 4 that, conversely, R-equivalence implies S-equivalence.

Figure 11. Two S-equivalent (but not R-equivalent) floorplans.

3.2. S-permutations

Let $P$ be a floorplan of size $n + 1$. There are $n$ segments in $P$. Let $S(P)$ be the sequence $b_1, b_2, \ldots, b_n$, where $b_i$ is the label in the $\prec$ order of the segment labeled $i$ in the $\succ$ order, for all $1 \leq i \leq n$. Then $S(P)$ is a permutation of $[n]$; we call it the S-permutation of $P$ and denote it by $S(P)$. Equivalently, if $I_1, \ldots, I_n$ is the list of segments in the $\preceq$ order, then $I_{\sigma^{-1}(1)}, \ldots, I_{\sigma^{-1}(n)}$ is the list of segments in the $\prec$ order, with $\sigma = S(P)$. Since the $\preceq$- and $\prec$-orders on segments can be determined in linear time (Proposition 2.11), the S-permutation is also constructed in linear time. An example is shown in Fig. 12.

Thus, we assign a permutation to a floorplan in a way similar to that used in [1], but this time we use order relations between segments rather than rectangles. Note that $S(P)$ is a permutation of $[n]$, while $R(P)$ is a permutation of $[n + 1]$.

By definition of $S(P)$, if a segment of $P$ is labeled $i$ in the $\preceq$ order and $j$ in the $\prec$ order, then $S(P)(i) = j$. In other words, the graph of $S(P)$ contains the point $(i, j)$, which will be denoted by $N_i$.

Figure 12. A floorplan $P$, with segments labeled $(i, j)$, where $i$ (respectively, $j$) is the label according to the $\preceq$ (respectively, $\prec$) order, and the corresponding S-permutation.

It follows from Proposition 2.12 that the map $S$ has a simple behavior with respect to symmetries.
Proposition 3.2. Let \( P \) be a (square) floorplan, and \( P' \) be obtained by reflecting \( P \) in the first diagonal. Let 
\[
\sigma = S(P) \quad \text{and} \quad \sigma' = S(P').
\]
Then \( \sigma' \) is obtained by reading \( \sigma \) from right to left or equivalently, by reflecting the graph of \( \sigma \) in a vertical line.

If instead \( P' \) is obtained by reflecting \( P \) in a horizontal line, then \( \sigma' = \sigma^{-1} \). Equivalently, \( \sigma' \) is obtained by reflecting the graph of \( \sigma \) in the first diagonal.

Proof. The following statements are equivalent:

- \( \sigma(i) = j \),
- there exists a segment of \( P \) that has label \( i \) in the \( \prec \)-order and \( j \) in the \( \succ \)-order (by definition of \( S \)),
- there exists a segment of \( P' \) that has label \( n + 1 - i \) in the \( \prec \)-order and \( j \) in the \( \succ \)-order (by Proposition 2.12),
- \( \sigma'(n + 1 - i) = j \).

This proves the first result. The proof of the second result is similar. \( \square \)

Since the two reflections of Proposition 3.2 generate the group of symmetries of the square, we can describe what happens for the other elements of this group: applying a rotation to \( P \) boils down to applying the same rotation to \( S(P) \), and reflecting \( P \) in \( \Delta \), a symmetry axis of the bounding square, boils down to reflecting \( S(P) \) in \( \Delta' \), a line obtained by rotating \( \Delta \) of 45° in counterclockwise direction. These properties will be extremely useful to decrease the number of cases we have to study in certain proofs.

We will now prove that \( S(P) \) characterizes the \( S \)-equivalence class of \( P \). Clearly, two \( S \)-equivalent floorplans give rise to the same orders, and thus to the same \( S \)-permutation. Conversely, let us define neighborhood relations between points in the graph of a permutation \( \sigma \) as follows. Let \( N_i = (i, \sigma(i)) \), \( N_j = (j, \sigma(j)) \) be two points in the graph of \( \sigma \). If \( i < j \) and \( \sigma(i) < \sigma(j) \), then the point \( N_j \) is to the NE of the point \( N_i \). In addition, there is no \( i' \) such that \( i < i' < j \) and \( \sigma(i) < \sigma(i') < \sigma(j) \), then \( N_j \) is a \( \text{NE-neighbor} \) of \( N_i \). In a similar way we define when \( N_j \) is to the \( \text{SE} / \text{SW} / \text{NW} \) of \( N_i \), and when the point \( N_j \) is a \( \text{SE-} / \text{SW-} / \text{NW-neighbor} \) of \( N_i \). For example, in the graph of Fig. 12, the points \( (1,7) \), \( (2,8) \), \( (3,6) \), \( (5,9) \) and \( (6,12) \) are to the NW of \( N_7 = (7,5) \); among them, \( (3,6) \), \( (5,9) \) and \( (6,12) \) are NW-neighbors of \( N_7 \).

The neighborhood relations between segments of \( P \) correspond to the neighborhood relations in the graph of \( S(P) \) in the following way.

Observation 3.3. Let \( P \) be a floorplan, and let \( I_i \) and \( I_j \) be two segments in \( P \).

The segment \( I_j \) is to the right of \( I_i \) if and only if the point \( N_j \) lies to the NE of \( N_i \). Consequently, \( I_j \) is a right-neighbor of \( I_i \) if and only if \( N_j \) is a NE-neighbor of \( N_i \).

Similar statements hold for the other directions: left (respectively, above, below) neighbors in segments correspond to SW- (respectively, NW-, SE-) neighbors in points.

Proof. The segment \( I_j \) is to the right of \( I_i \) if and only if \( I_i \not\prec I_j \) and \( I_i \not\succ I_j \). By construction of \( \sigma = S(P) \), this means that \( i < j \) and \( \sigma(i) < \sigma(j) \). Equivalently, \( N_j \) lies to the NE of \( N_i \). \( \square \)

Remark. An analogous fact holds for rectangles of a floorplan and points in the graph of the corresponding \( R \)-permutation. It is not stated explicitly in \cite{11}, but follows directly from the definitions in the same way as Observation 3.3 does.

Since the neighborhood relations characterize the \( S \)-equivalence class, we have proved the following result.

Corollary 3.4. Two floorplans are \( S \)-equivalent if and only if they have the same \( S \)-permutation.

3.3. (2-14-3, 3-41-2)-Avoiding permutations

In this section we first discuss the dash notation and bar notation for pattern avoidance in permutations, and then prove several facts about (2-14-3, 3-41-2)-avoiding permutations. As will be proved in Section 3.4 these are precisely the \( S \)-permutations obtained from floorplans.
In the classical notation, a permutation \( \pi = a_1 a_2 \ldots a_n \) avoids a permutation (a pattern) \( \tau = b_1 b_2 \ldots b_k \) if there are no \( 1 \leq i_1 < i_2 < \ldots < i_k \leq n \) such that \( a_{i_1} a_{i_2} \ldots a_{i_k} \) (a subpermutation of \( \pi \)) is order isomorphic to \( \tau \) (\( b_a < b_y \) if and only if \( a_{i_x} < a_{i_y} \)).

The dash notation and the bar notation generalize the classical notation and provide a convenient way to define more classes of restricted permutations. For a recent survey, see \[35\].

In the dash notation, some letters corresponding to those from the pattern \( \tau \) may be required to be adjacent in the permutation \( \pi \), in the following way. If there is a dash between two letters in \( \tau \), the corresponding letters in \( \pi \) may occur at any distance from each other; if there is no dash, they must be adjacent in \( \pi \). For example, \( \pi = a_1 a_2 \ldots a_n \) avoids 2-14-3 if there are no \( 1 \leq i < j < \ell < m \) such that \( \ell = j + 1 \) and \( a_j < a_i < a_m < a_{\ell} \).

In the bar notation, some letters of \( \tau \) may have bars. A permutation \( \pi \) avoids a barred pattern \( \tau \) if every occurrence of the unbarred part of \( \tau \) is a sub-occurrence of \( \pi \) (with bars removed). For example, \( \pi = a_1 a_2 \ldots a_n \) avoids 21354 if for any \( 1 \leq i < j < \ell < m \) such that \( a_j < a_i < a_m < a_{\ell} \), there exists \( k \) such that \( j < k < \ell \) and \( a_i < a_k < a_m \) (any occurrence of the pattern 2154 is a sub-occurrence of the pattern 21354).

A (reduced) Baxter permutation is a permutation of \([n]\) satisfying the following condition:

There are no \( i, j, \ell, m \in [n] \) satisfying \( i < j < \ell < m, \ell = j + 1 \), such that either \( \pi(j) < \pi(m) < \pi(i) < \pi(\ell) \) and \( \pi(i) = \pi(m) + 1 \), or \( \pi(\ell) < \pi(i) < \pi(m) < \pi(j) \) and \( \pi(m) = \pi(i) + 1 \).

In the dash notation, Baxter permutations are those avoiding \((241-3, 314-2)\), and in the bar notation, Baxter permutations are those avoiding \((41352, 25314)\) (see \[21\] or \[35, Sec. 7\]). As proved in \[1\], the permutations that are obtained as R-permutations are precisely the Baxter permutations. It turns out that the permutations that are obtained as S-permutations may be defined by similar conditions, given below in Proposition \[3.6\] As in the Baxter case, these conditions can be defined in three different ways.

**Lemma 3.5.** Let \( \pi \) be a permutation of \([n]\). The following conditions are equivalent:

1. There are no \( i, j, \ell, m \in [n] \) such that \( i < j < \ell < m, \ell = j + 1 \), \( \pi(j) < \pi(i) < \pi(m) < \pi(\ell) \), \( \pi(\ell) = \pi(i) + 1 \).
2. In the dash notation, \( \pi \) avoids 2-14-3.
3. In the bar notation, \( \pi \) avoids 21354.

Fig. 13 illustrates these three conditions. The rows (respectively, columns) marked by dots in parts (1) and (2) denote adjacent rows (respectively, columns). The shaded area in part (3) does not contain points of the graph.

**Figure 13.** Three ways to define permutations avoiding 2-14-3.

**Proof.** It is clear that \( 3 \Rightarrow 2 \Rightarrow 1 \): the four points displayed in Fig. 13(1) form an occurrence of the pattern of Fig. 13(2), and the four points displayed in Fig. 13(2) form an occurrence of the pattern of Fig. 13(3).
Conversely, let us prove that if a permutation $\pi$ contains the pattern 21354, then there exist $i', j', \ell', m'$ as in the first condition. Assume that there are $i < j < \ell < m$ such that $\pi(j) < \pi(i) < \pi(m) < \pi(\ell)$, and there is no $k$ such that $j < k < \ell$ and $\pi(i) < \pi(k) < \pi(m)$. Let $j'$ be the maximal number for which $j \leq j' < \ell$ and $\pi(j') < \pi(i)$. Let $\ell' = j' + 1$. Then $\pi(\ell') > \pi(m)$, and we have a pattern 2-14-3 with $i, j', \ell', m$.

Furthermore, let $i'$ be the number satisfying $i' < j'$ and $\pi(i) < \pi(i') < \pi(m)$, for which $\pi(i')$ is the maximal possible. Let $m' = \pi^{-1}(\pi(i') + 1)$. Then $m' > \ell'$ and $\pi(m') = \pi(i') + 1$, and, thus, the first condition holds with $i', j', \ell', m'$.

A similar result holds for permutations that avoid 3-41-2. Therefore, the following proposition holds.

**Proposition 3.6.** Let $\sigma$ be a permutation of $[n]$. The following statements are equivalent:

1. There are no $i, j, \ell, m \in [n]$ satisfying $i < j < \ell < m$, $\ell = j + 1$, such that $\sigma(j) < \sigma(i) < \sigma(m) < \sigma(\ell)$ and $\sigma(m) = \sigma(i) + 1$;
2. In the dash notation, $\sigma$ avoids 2-14-3 and 3-41-2;
3. In the bar notation, $\sigma$ avoids 21354 and 45312.

**Corollary 3.7.** The group of symmetries of the square leaves invariant the set of (2-14-3, 3-41-2)-avoiding permutations.

**Proof.** The second description in Proposition 3.6 shows that the set of (2-14-3, 3-41-2)-avoiding permutations is closed under reading the permutations from right to left. The first (or third) description shows that it is invariant under taking inverses, and these two transformations generate the symmetries of the square.

We shall also use the following fact.

**Lemma 3.8.** Let $\sigma$ be a (2-14-3, 3-41-2)-avoiding permutation of $[n]$. Then no point in the graph of $\sigma$ has several NW-neighbors and several NE-neighbors. Similar statements hold for other pairs of adjacent diagonal directions.

**Proof.** Assume that $N_i = (i, \sigma(i))$ has several NW-neighbors and several NE-neighbors. Let $i'$ be the maximal number for which $N_{i'}$ is a NW-neighbor of $N_i$, and let $N_j$ be another NW-neighbor of $N_i$. Then we have $j < i'$ and $\sigma(i) < \sigma(j) < \sigma(i')$. We conclude that $i' = i - 1$: otherwise $\sigma(i' + 1) < \sigma(i)$ and, therefore, $j, i', i' + 1, i$ form the forbidden pattern 3-41-2, which is a contradiction.

Similarly, if $i''$ is the minimal number for which $N_{i''}$ is a NE-neighbor of $N_i$, then $i'' = i + 1$. Let $N_k$ be another NE-neighbor of $N_i$. We have $\sigma(i) < \sigma(k) < \sigma(i + 1)$.

Assume without loss of generality that $\sigma(i - 1) < \sigma(i + 1)$. Now, if $\sigma(j) < \sigma(k)$, then $j, i, i + 1, k$ form the forbidden pattern 2-14-3; and if $\sigma(k) < \sigma(j)$, then $j, i - 1, i, k$ form the forbidden pattern 3-41-2, which is, again, a contradiction.

### 3.4. S-permutations coincide with (2-14-3, 3-41-2)-avoiding permutations

By Corollary 3.4, the map $S$ induces an injection from S-equivalence classes of floorplans to permutations. Here, we characterize the image of $S$.

**Theorem 3.9.** The map $S$ induces a bijection between S-equivalence classes of floorplans of size $n + 1$ and (2-14-3, 3-41-2)-avoiding permutations of size $n$.

The proof involves two steps: In Proposition 3.11 we prove that all S-permutations are (2-14-3, 3-41-2)-avoiding. Then, in Proposition 3.12, we show that for any (2-14-3, 3-41-2)-avoiding permutation $\sigma$ of $[n]$, there exists a floorplan $P$ with $n$ segments such that $S(P) = \sigma$.

Recall that a horizontal segment has at most one left-neighbor and at most one right-neighbor, and a vertical segment has at most one below-neighbor and at most one above-neighbor. This translates as follows in terms of S-permutations.
Observation 3.10. Let $I_i$ be a segment in a floorplan $P$, and let $N_i$ be the corresponding point in the graph of $S(P)$. If $I_i$ is a horizontal segment, then the point $N_i$ has at most one NE-neighbor and at most one SW-neighbor. Similarly, if $I_i$ is a vertical segment, then $N_i$ has at most one SE-neighbor and at most one NW-neighbor.

Proposition 3.11. Let $P$ be a floorplan. Then $S(P)$ avoids 2-14-3 and 3-41-2.

Proof. By Proposition 3.2 the image of $S$ is invariant by all symmetries of the square. Hence it suffices to prove that $\sigma = S(P)$ avoids 2-14-3.

Assume that $\sigma$ contains 2-14-3. By Lemma 3.5 there exist $i < j < \ell < m$, $\ell = j + 1$ such that $\sigma(j) < \sigma(i) < \sigma(m) < \sigma(\ell)$ and $\sigma(m) = \sigma(i) + 1$ (see Fig. 14(1)). We claim that the four segments $I_i, I_j, I_\ell, I_m$ are vertical.

Consider $I_j$. The point $N_j$ is a NE-neighbor of $N_i$. Consider the set $\{x: x > \ell, \sigma(j) < \sigma(x) < \sigma(\ell)\}$. This set is not empty since it contains $m$. Let $p$ be the smallest element in this set. Then $N_p$ is a NE-neighbor of $N_j$. Thus, $N_j$ has at least two NE-neighbors, $N_\ell$ and $N_p$. Therefore, $I_j$ is vertical by Observation 3.10. In a similar way one can show that $I_i, I_\ell, I_m$ are also vertical.

![Figure 14](image)

The pattern 2-14-3 never occurs in an S-permutation.

By Observation 3.3 we have that: $I_j \downarrow I_i, I_m \downarrow I_\ell; I_i \leftarrow I_\ell, I_j \leftarrow I_m, I_\ell \leftarrow I_m, I_j \leftarrow I_\ell$. Moreover, the last two relations are neighborhood relations. Let $I_k$ be the below-neighbor of $I_i$, and let $I_{k'}$ be the below-neighbor of $I_\ell$ (see Fig. 14(2)). The segments $I_k$ and $I_{k'}$ are horizontal. If the line supporting $I_k$ is (weakly) lower than the line supporting $I_{k'}$, then $I_j$ (which is below $I_i$) cannot be a left-neighbor of $I_\ell$ since the interiors of their vertical projections do not intersect. Similarly, if the line supporting $I_k$ is higher than the line supporting $I_{k'}$, then $I_j$ cannot be a left-neighbor of $I_m$. We have thus reached a contradiction, and $\sigma$ cannot contain 2-14-3.

Proposition 3.12. For each (2-14-3, 3-41-2)-avoiding permutation $\sigma$ of $[n]$, there exists a floorplan $P$ with $n$ segments such that $S(P) = \sigma$.

Proof. We construct $P$ on the graph of $\sigma$. The boundary of the graph is also the boundary of $P$. For each point $N_i = (i, \sigma(i))$ of the graph, we draw a segment $K_i$ passing through $N_i$ according to certain rules. We first determine the direction of the segments $K_i$ (Paragraph A below), and then the coordinates of their endpoints (Paragraph B). We prove that we indeed obtain a floorplan (Paragraph C), and that its S-permutation is $\sigma$ (Paragraph D). This is probably one of the most involved proofs of the paper.

A. Directions of the segments $K_i$.

Let $N_i = (i, \sigma(i))$ be a point in the graph of $\sigma$. Our first two rules are forced by Observation 3.10. They are illustrated in Fig. 15 (no point of the graph lies in the shaded areas):

- If $N_i$ has several NW-neighbors or several SE-neighbors, then $K_i$ is horizontal.
ORDERS INDUCED BY SEGMENTS IN FLOORPLANS

• If $N_i$ has several SW-neighbors or several NE-neighbors, then $K_i$ is vertical.

By Lemma 3.8, these two rules never apply simultaneously to the same point $N_i$. If one of them applies, we say that $N_i$ is a strong point. Otherwise, $N_i$ is a weak point. This means that $N_i$ has at most one neighbor in each direction.

We claim that if $N_i$ and $N_j$ are weak points, then they are in adjacent rows if and only if they are in adjacent columns. Due to symmetry, it suffices to show the if direction. Let $N_i$ and $N_{i+1}$ be weak points, and assume without loss of generality that $\sigma(i) < \sigma(i + 1)$. If $\sigma(i + 1) - \sigma(i) > 1$, then there are points of the graph of $\sigma$ between the rows that contain $N_i$ and $N_{i+1}$; thus, either $N_i$ has at least two NE-neighbors or $N_{i+1}$ has at least two SW-neighbors, which means that one of them at least is strong. Hence $\sigma(i + 1) = \sigma(i) + 1$.

Thus, weak points appear as ascending or descending sequences of adjacent neighbors: $N_i, N_{i+1}, \ldots, N_{i+\ell}$ with $\sigma(i) = \sigma(i + 1) - 1 = \cdots = \sigma(i + \ell) - \ell$ or $\sigma(i) = \sigma(i + 1) + 1 = \cdots = \sigma(i + \ell) + \ell$. Note that a weak point $N_i$ can be isolated.

For weak points, the direction of the corresponding segments is determined as follows:

• If $N_i, N_{i+1}, \ldots, N_{i+\ell}$ is a maximal ascending sequence of weak points, then the directions of $K_i, K_{i+1}, \ldots, K_{i+\ell}$ are chosen in such a way that $K_j$ and $K_{j+1}$ are never both horizontal, for $i \leq j < i + \ell$. Hence several choices are possible (this multiplicity of choices is consistent with the fact that all S-equivalent floorplans give the same permutation).

• If $N_i, N_{i+1}, \ldots, N_{i+\ell}$ is a maximal descending sequence of weak points, then the directions of $K_i, K_{i+1}, \ldots, K_{i+\ell}$ are chosen in such a way that $K_j$ and $K_{j+1}$ are never both vertical, for $i \leq j < i + \ell$.

In particular, for an isolated weak point $N_i$, the direction of $K_i$ can be chosen arbitrarily.

B. Endpoints of the segments $K_i$.

Once the directions of all $K_i$’s are chosen, their endpoints are set as follows (see Fig. 14 for an illustration):

• If $K_i$ is vertical (which implies that $N_i$ has at most one NW-neighbor and at most one SE-neighbor):
  – If $N_i$ has a NW-neighbor $N_j$, then the upper endpoint of $K_i$ is set to be $(i, \sigma(j))$. We say that $N_j$ bounds $K_i$ from above. Otherwise (if $N_i$ has no NW-neighbor), $K_i$ reaches the upper side of the boundary.
  – If $N_i$ has a SE-neighbor $N_k$, then the lower endpoint of $K_i$ is $(i, \sigma(k))$. We say that $N_k$ bounds $K_i$ from below. Otherwise, $K_i$ reaches the lower side of the boundary.

• If $K_i$ is horizontal (which implies that $N_i$ has at most one SW-neighbor and at most one NE-neighbor):
  – If $N_i$ has a SW-neighbor $N_j$, then the left endpoint of $K_i$ is $(j, \sigma(i))$. We say that $N_j$ bounds $K_i$ from the left. Otherwise, $K_i$ reaches the left side of the boundary.
  – If $N_i$ has a NE-neighbor $N_k$, then the right endpoint of $K_i$ is $(k, \sigma(i))$. We say that $N_k$ bounds $K_i$ from the right. Otherwise, $K_i$ reaches the right side of the boundary.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{image15.png}
\caption{Rules for determining the direction of the segment $K_i$ passing through a strong point.}
\end{figure}
Figure 16. Determining the endpoints of the segment $K_i$: the points $N_j$ and $N_k$ bound the segment $K_i$.

Fig. 17 presents an example of the whole construction: in Part 1, the directions are determined for strong (black) points, and chosen for weak (gray) points; in Part 2, the endpoints are determined and a floorplan is obtained. Notice that $\sigma$ is the S-permutation associated with the floorplan $P$ of Fig. 12 but here we have obtained a different floorplan, $P'$. We leave it to the reader to check that another choice of directions of segments passing through weak points leads to $P$.

The question of when $S(P) = S(P')$ will be studied in Section 4.2.

Remark. Using dynamic programming, one can determine in linear time the values

$$m_i = \max \{ k < i : \sigma(k) < \sigma(i) \} \cup \{0\} \quad \text{and} \quad M_i = \max \{ k < i : \sigma(k) > \sigma(i) \} \cup \{0\}.$$  

By applying this procedure to $\sigma$ and to the permutations obtained by applying to $\sigma$ a symmetry of the square, one can decide in linear time, for each point $N_i$ of $\sigma$, if it has one or several NW-neighbours and locate one of them. This implies that the above construction of a floorplan starting from a (2-14-3, 3-41-2)-avoiding permutation can be done in linear time.

C. The construction indeed determines a floorplan.

In order to prove this, we need to show that two segments never cross, and that the endpoints of any segment $K_i$ are contained in segments perpendicular to $K_i$ (unless they lie on the boundary). The following observation will simplify some of our proofs.

Observation 3.13. Let $\sigma$ be a (2-14-3, 3-41-2)-avoiding permutation, and let $\sigma'$ be obtained by applying a rotation $\rho$ (a quarter turn or a half-turn, clockwise or counterclockwise) to (the graph of) $\sigma$. If $P$ is a
configuration of segments obtained from \( \sigma \) by applying the rules of Paragraphs A and B above, then \( \rho(P) \) can be obtained from \( \sigma' \) using those rules.

To prove this, it suffices to check that the rules are invariant by a \( 90^\circ \) rotation, which is immediate.\footnote{That the construction has the other symmetries of Proposition 6.3 is also true, but less obvious. We shall only use Observation 6.13}

C.1. Let \( K_i \) be a vertical (respectively, horizontal) segment, and let \( N_j \) and \( N_k \) be the points that bound it. Then the segments \( K_j \) and \( K_k \) are horizontal (respectively, vertical).

Thanks to Observation 3.13 it suffices to prove this claim for a vertical segment \( K_i \) and for the point \( N_j \) that bounds it from above. We need to prove that \( K_j \) is a horizontal segment.

We have \( j < i \) and \( \sigma(i) < \sigma(j) \), and, since \( N_j \) is a NW-neighbor of \( N_i \), there is no \( \ell \) such that \( j < \ell < i \) and \( \sigma(i) < \sigma(\ell) < \sigma(j) \). Furthermore, there is no \( \ell \) such that \( j < \ell < i \), \( \sigma(j) < \sigma(\ell) \), or such that \( \ell < j \), \( \sigma(i) < \sigma(\ell) < \sigma(j) \): otherwise \( N_i \) would have several NW-neighbors and, therefore, \( K_i \) would be horizontal.

Now, if \( i - j > 1 \), then there exists \( \ell \) such that \( j < \ell < i \), \( \sigma(\ell) < \sigma(i) \); and if \( \sigma(j) - \sigma(i) > 1 \), then there exists \( m \) such that \( i < m \), \( \sigma(i) < \sigma(m) < \sigma(j) \). In both cases \( N_j \) has several SE-neighbors, and, therefore, \( K_j \) is horizontal as claimed.

It remains to consider the case where \( j = i - 1 \) and \( \sigma(j) = \sigma(i) + 1 \). If the point \( N_i \) is strong, then (since \( K_i \) is vertical) it has several NE-neighbors or several SW-neighbors. Assume without loss of generality that \( N_i \) has several NE-neighbors. Let \( \ell \) be the minimal number such that \( N_i \) is a NE-neighbor of \( N_i \), and let \( N_m \) be another NE-neighbor of \( N_i \). Then we have \( \sigma(i - 1) < \sigma(m) < \sigma(\ell) \) and \( \sigma(\ell - 1) < \sigma(i) \). However, then \( i - 1, \ell - 1, \ell, m \) form a forbidden pattern 2-14-3. Therefore, \( N_i \) is a weak point. Clearly, \( N_{i-1} \) as a unique SE-neighbor (which is \( N_i \)). Its NE- and SW-neighbors coincide with those of \( N_i \), so that there is at most one of each type. Thus if \( N_{i-1} \) is strong, it has several NW-neighbors, and \( K_{i-1} \) is horizontal, as claimed. If \( N_{i-1} \) is weak, then the rules that determine the direction of the segments passing through (descending) weak points implies that \( K_{i-1} \) and \( K_i \) cannot be both vertical. Therefore, \( K_j = K_{i-1} \) is horizontal, as claimed.

C.2. If \( N_j \) and \( N_k \) are the points that bound the segment \( K_i \), then the segments \( K_j \) and \( K_k \) contain the endpoints of \( K_i \).

Thanks to Observation 3.13 it suffices to show that if \( K_i \) is a vertical segment and \( N_j \) bounds it from above, then \( K_j \) (which is horizontal as shown in Paragraph C.1 above) contains the point \( (i, \sigma(i)) \). We saw in Paragraph C.1 that in this situation there is no \( \ell \) such that \( j < \ell < i \), \( \sigma(j) < \sigma(\ell) \). This means that there is no point \( N_\ell \) that could bound \( K_j \) from the right before it reaches \( (i, \sigma(j)) \).

C.3. Two segments \( K_i \) and \( K_j \) cannot cross

Assume that \( K_i \) and \( K_j \) cross. Assume without loss of generality that \( K_i \) is vertical and \( K_j \) is horizontal, so that their crossing point is \( (i, \sigma(j)) \). We have either \( i < j \) or \( j < i \), and \( \sigma(i) < \sigma(j) \) or \( \sigma(j) < \sigma(i) \). Assume without loss of generality \( j < i \) and \( \sigma(i) < \sigma(j) \). Then \( N_j \) is to the NW of \( N_i \). The ordinate of the (unique) NE-neighbor of \( N_i \) is hence at most \( \sigma(j) \). By construction, the upper point of \( K_i \) has ordinate at most \( \sigma(j) \), while \( K_j \) lies at ordinate \( \sigma(j) \), and thus \( K_i \) and \( K_j \) cannot cross.

We have thus proved that our construction indeed gives a floorplan. Let us finish with an observation on joins of segments of this floorplan, which follows from Paragraph C.2 and is illustrated below.

Observation 3.14. Suppose that a vertical segment \( K_i \) and a horizontal segment \( K_j \) join at the point \( (i, \sigma(j)) \). Then:

- If the join of \( K_i \) and \( K_j \) is of the type \( \tau \), then \( i > j \).
- If the join of \( K_i \) and \( K_j \) is of the type \( \iota \), then \( i < j \).
- If the join of \( K_i \) and \( K_j \) is of the type \( \tau^- \), then \( \sigma(i) < \sigma(j) \).
- If the join of \( K_i \) and \( K_j \) is of the type \( \iota^- \), then \( \sigma(i) > \sigma(j) \).
D. For any floorplan \( P \) obtained by the construction described above, \( S(P) = \sigma. \)

This (concluding) part of the proof is given in Appendix A. \( \square \)

4. Relations between the R- and S-permutations

In this section we prove that if two floorplans are R-equivalent, they are S-equivalent (that is, the R-equivalence refines the S-equivalence). In fact, we give a simple graphical way to construct \( S(P) \) from \( R(P) \), which also shows that \( S(P) \) and \( R(P) \) taken together form the complete Baxter permutation associated with the reduced Baxter permutation \( R(P) \). Finally, we characterize the R-equivalence classes that belong to the same S-equivalence class.

4.1. Constructing \( S(P) \) from \( R(P) \)

Let \( P \) be a floorplan of size \( n + 1 \). We draw the graphs of \( \rho = R(P) \) and \( \sigma = S(P) \) on the same diagram in the following way (Fig. 18). For the graph of \( \rho \) we use an \((n+1) \times (n+1)\) square whose columns and rows are numbered by 1, 2, \ldots, \( n + 1 \). The points of the graph of \( \rho \) are placed at the centers of these squares, and these points are black. For the graph of \( \sigma \) we use the grid lines of the same drawing, when the \( i \)-th vertical (respectively, horizontal) line is the grid line between the \( i \)-th and the \((i + 1)\)-st columns (respectively, rows). The point \((i, \sigma(i))\) is placed at the intersection of the \( i \)-th vertical grid line and the \( j \)-th horizontal grid line, where \( j = \sigma(i) \). Such points are white. The whole drawing is called the combined diagram of \( P \). Note that the extreme (rightmost, leftmost, etc.) grid lines are not used.

\[ \begin{align*}
\text{Rectangles} & \quad \text{Segments} & \quad \text{Combined diagram}
\end{align*} \]

**Figure 18.** The floorplan \( P \) from Fig. 12: (1) The labeling of rectangles; (2) The labeling of segments; (3) The combined diagram: \( R(P) = 8 7 9 1 6 13 10 3 2 5 4 12 11 \) (black points) together with \( S(P) = 7 8 6 1 9 12 5 2 3 4 10 11 \) (white points).

**Definition 4.1.** Let \( \rho \) be a Baxter permutation of \([n + 1]\). For \( 1 \leq i \leq n \), define \( j_i \) as follows:

- if \( \rho(i) < \rho(i + 1) \), then \( j_i = \max\{\rho(k), k \leq i \text{ and } \rho(k) < \rho(i + 1)\} \),
- if \( \rho(i) > \rho(i + 1) \), then \( j_i = \max\{\rho(k), k \geq i + 1 \text{ and } \rho(k) < \rho(i)\} \).
The definition of Baxter permutations implies that

- if $\rho(i) < \rho(i+1)$, $k \geq i+1$ and $\rho(k) > \rho(i)$, then $\rho(k) > \rho(j_i)$,
- if $\rho(i) > \rho(i+1)$, $k \leq i$ and $\rho(k) > \rho(i+1)$, then $\rho(k) > \rho(j_i)$.

**Theorem 4.2.** Let $P$ be a floorplan of size $n+1$, and let $\rho = R(P)$. Then $S(P) = (j_1, j_2, \ldots, j_n)$, where $j_i$ is defined in Definition 4.1. In particular, R-equivalent floorplans are also $S$-equivalent.

Returning to the original papers on Baxter permutations (see for instance [11] Thm. 2], or the definition of complete permutations in [12] p. 180]) this means that the combined diagram forms a (complete) Baxter permutation $\pi$. The points of $R(P)$ form the reduced Baxter permutation $\pi_o$ associated with $\pi$, and the points of $S(P)$ are those that are deleted from $\pi$ when constructing $\pi_o$.

**Proof.** Let $i \in [n]$. Denote $\sigma = S(P)$ and $j = \sigma(i)$. Then the segment $I_i$ labeled $i$ in the $\kappa$ order, is labeled $j$ in the $\kappa'$ order. We denote by $A_k$ (resp. $B^k$) the $k$th rectangle in the $\kappa'$ (resp. $\kappa'$-) order. We wish to prove that $j = j_i$.

Assume first that $I_i$ is horizontal. By Observation 2.11, the rightmost rectangle whose lower side is contained in $I_i$ is $A_i$, and the leftmost rectangle whose upper side is contained in $I_i$ is $A_{i+1}$ (Fig. 19).

By definition of $\rho$, we have $A_k = B^\rho(k)$ for all $k$. By symmetry, since $I_i$ is the $j$th segment in the $\kappa'$ order, the rightmost rectangle whose upper side is contained in $I_i$ is $B^j$, and the leftmost rectangle whose lower side is contained in $I_i$ is $B^{j+1}$. There holds $A_{i+1} \not\prec B^j \prec B^{j+1} \not\prec A_i$ and $B^{j+1} \not\prec A_i \not\prec A_{i+1} \not\prec B^j$. By definition of $\rho = R(P)$, this means $\rho(i) \leq j < j+1 \leq \rho(i)$ and $\rho^{-1}(j+1) \leq i < i+1 \leq \rho^{-1}(j)$. This shows that $j$ coincides with the value $j_i$ of Definition 4.1 (for the case $\rho(i) > \rho(i+1)$).

The case where $I_i$ is vertical is similar, and corresponds to an ascent in $\rho$. \hfill \qed

**Figure 19.** Illustration of the proof of Theorem 4.2

The symmetry in the definition of $j_i$ makes the following property obvious, without going through floorplans.

**Corollary 4.3.** Let $P$ be a floorplan and let $\rho = R(P)$ be the corresponding Baxter permutation. Let us abuse notation by denoting $S(\rho) := S(P)$. If $\rho'$ is obtained by applying to $\rho$ a symmetry of the square, then the same symmetry, applied to $S(\rho')$, gives $S(\rho)$.

**Remark.** The combined diagram is actually the $R$-permutation of a floorplan of size $2n+1$. Indeed, let $P$ be a floorplan of size $n+1$. If we inflate segments of $P$ into narrow rectangles, we obtain a new floorplan of size $2n+1$, which we denote by $\hat{P}$ (Fig. 20). Observe that a rectangle of $\hat{P}$ corresponding to a rectangle $A$ of $P$ has a unique above (respectively, right, below, left) neighbor, which corresponds to the segment of $\hat{P}$ that contains the above (respectively, right, below, left) side of $A$.

It follows from Observation 2.11 and Fig. 9 that the $\kappa$ order in $\hat{P}$ is $A_1 I_1 A_2 I_2 \ldots A_n I_n A_{n+1}$. It is thus obtained by shuffling the $\kappa$ orders for rectangles and segments of $P$. Symmetrically, the $\kappa'$ order in $\hat{P}$ is $A_{n+1} I_{n+1} A_n I_n \ldots A_2 I_2 A_1$. Thus the combined diagram of $R(P)$ and $S(P)$, as in Fig. 18, coincides with the graph of $R(\hat{P})$. 

4.2. Floorplans that produce the same S-permutation

In this section we characterize in terms of their R-permutations the floorplans that have the same S-permutation. This will play a central role in the enumeration of S-permutations.

We first describe the floorplans whose S-permutation is 123...n. Such floorplans will be called ascending F-blocks. It is easy to see that in an ascending F-block, all vertical segments extend from the lower to the upper side of the boundary, and there is at most one horizontal segment between a pair of adjacent vertical segments (this can be shown inductively, by noticing that at most one horizontal segment starts from the left side of the bounding rectangle). See Fig. 21. Conversely, every floorplan of this type has S-permutation 123...n. Therefore, an ascending F-block consists of several rectangles that extend from the lower to the upper side of the boundary, some of them being split into two sub-rectangles by a horizontal segment. The corresponding R-permutations are those that satisfy \(|\rho(i) - i| \leq 1\) for all \(1 \leq i \leq n + 1\). The number of ascending F-blocks of size \(n + 1\) (and, therefore, the number of such permutations) is the Fibonacci number \(F_{n+1}\) (where \(F_0 = F_1 = 1\)).

![Ascending F-blocks for n=4](image)

A similar observation holds for the floorplans whose S-permutation is n...321. Such floorplans are called descending F-blocks. In descending F-blocks, all horizontal segments extend from the left side to the right side of the boundary, and there is at most one vertical segment between a pair of adjacent horizontal segments. In other words, descending F-blocks consist of several rectangles that extend from the left to the right side of the boundary, some of them being split into two sub-rectangles by a vertical segment. The corresponding R-permutations are characterized by the condition \(|\rho(i) - (n + 2 - i)| \leq 1\) for all \(1 \leq i \leq n + 1\).

For an F-block \(F\), the size of \(F\) (that is, the number of rectangles) will be denoted by \(|F|\). If \(|F| = 1\), we say that \(F\) is a trivial F-block. Note that if \(|F| \leq 2\), then \(F\) is both ascending and descending, while if \(|F| \geq 3\), then its type (ascending or descending) is uniquely determined.

\(^9\)The letter F refers to Fibonacci, for reasons that will be explained further down.
Let $P$ be a floorplan. We define an \textit{F-block} in $P$ as a set of rectangles of $P$ whose union is an F-block, as defined above. In other words, their union is a rectangle, and the S-permutation of the induced subpartition is either $123\ldots$ or $\ldots321$. The F-blocks of $P$ are partially ordered by inclusion. Since segments of $P$ do not cross, a rectangle in $P$ belongs precisely to one maximal F-block (which may be of size 1). So there is a uniquely determined partition of $P$ into maximal F-blocks (Fig. 22 left).

A \textit{block} in a permutation $\rho$ is an interval $[i,j]$ such that the values $\{\rho(i), \ldots, \rho(j)\}$ also form an interval [3]. By extension, we also call a block the corresponding set of points in the graph of $\rho$. Consider $\ell$ rectangles in $P$ that form an ascending (respectively, descending) F-block. By Observation 2.11 and the analogous statement for the $\prec$ order, these $\ell$ rectangles form an interval in the $\prec$ and $\prec$ orders. Hence the corresponding $\ell$ points of the graph of $R(P)$ form a block, and their inner order is isomorphic to a permutation $\tau$ of $[\ell]$ that satisfies $|\tau(i) - i| \leq 1$ (respectively, $|\tau(i) - (\ell + 1 - i)| \leq 1$) for all $1 \leq i \leq \ell$.

The converse is also true: If $\ell$ points of the graph of $R(P)$ form an $\ell \times \ell$ block, and their inner order is isomorphic to a permutation $\tau$ of $[\ell]$ that satisfies $|\tau(i) - i| \leq 1$ (respectively, $|\tau(i) - (\ell + 1 - i)| \leq 1$) for all $1 \leq i \leq \ell$, then the corresponding rectangles in $P$ form an ascending (respectively, descending) F-block. Indeed, let $H$ be such an ascending block in the graph of $R(P)$. Let us partition the points of $H$ in singletons (formed of points that lie on the diagonal) and pairs (formed of transposed points at adjacent positions). Let $Q_1, Q_2, \ldots$ be the parts of this partition, read from the SW to the NE corner of $H$. For each $i = 1, 2, \ldots$, the point(s) of $Q_{i+1}$ are the only NE-neighbors of the point(s) of $Q_i$, and, conversely, the point(s) of $Q_i$ are the only SW-neighbors of the point(s) of $Q_{i+1}$. Therefore, by the remark that follows Observation 3.3, the left side of the rectangle(s) corresponding to the point(s) of $Q_{i+1}$ coincides with the right side of the rectangle(s) corresponding to the point(s) of $Q_i$. If $Q_i$ consists of two points then we have two rectangles whose union is a rectangle split by a horizontal segment. The argument is similar for a descending block.

Therefore, such blocks in the graph of $\rho$ will be also called ascending (respectively, descending) F-blocks. Fig. 22 shows a floorplan with maximal F-blocks denoted by bold lines, and the F-blocks in the corresponding permutation $R(P)$ (the graph of $S(P)$ is also shown).

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{floorplan.png}
\caption{Maximal F-blocks in floorplans and in permutations.}
\end{figure}

Let $F_1, F_2, \ldots$ be all the maximal F-blocks in the graph of $\rho$ (ordered from left to right). For $i \geq 1$, let $[y_i, y'_i]$ be the interval of values $\rho(j)$ occurring in $F_i$, and define $d_i := +$ if $F_i$ is ascending, and $d_i := -$ if $F_i$ is descending ($d_i$ is left undefined if $F_i$ has size 1 or 2). The \textit{F-structure} of $\rho$ is the sequence $\bar{F}_1, \bar{F}_2, \ldots$, where $\bar{F}_i = ([y_i, y'_i], d_i)$. For example, the F-structure of the permutation in Fig. 22 is

\begin{align*}
([7,9], +), & \ (\{1\}), \ (\{6\}), \ (\{13\}), \ (\{10\}), \ (\{2, 5\}, +), \ (\{11, 12\}).
\end{align*}
Theorem 4.4. Let $P_1$ and $P_2$ be two floorplans with $n$ segments. Then $S(P_1) = S(P_2)$ if and only if $R(P_1)$ and $R(P_2)$ have the same F-structure.

In other words, $S(P_1) = S(P_2)$ if and only if $R(P_1)$ and $R(P_2)$ may be obtained from each other by replacing some F-blocks $F_1, F_2, \ldots$ with, respectively, F-blocks $F'_1, F'_2, \ldots$, where $F_i$ is S-equivalent to $F'_i$ for all $i$.

Proof. The “if” direction is easy to prove. Assume $R(P_1)$ and $R(P_2)$ have the same F-structure. In view of the way one obtains $S(P)$ from $R(P)$ (Theorem 4.2), we have $S(P_1) = S(P_2)$. Observe in particular that inside a maximal F-block of $R(P)$, the points of $S(P)$ are organized on the diagonal (in the ascending case) or the anti-diagonal (in the descending case).

In order to prove the “only if” direction, we will first relate, for a point of $S(P)$, the fact of being inside a maximal F-block to the property of being weak. (Recall that a point $N_i$ in the graph of $S(P)$ is weak if it has at most one neighbor in each of the directions NW, NE, SE, SW, and strong otherwise.) If a maximal F-block of $R(P)$ occupies the area $[x, x'] \times [y, y']$, then the point $N_i = (i, j)$ is inside this block if $x \leq i < x'$ and $y \leq j < y'$. For example, in Fig. 22 six points in the graph of $S(P)$ (the white points in the combined diagram) are inside a maximal F-block: $(1,7)$, $(2,8)$, $(8,2)$, $(9,3)$, $(10,4)$ and $(12,11)$. Observe that the notion of “being inside” a maximal F-block is a priori relative to $R(P)$. However, the following proposition shows that it is an intrinsic notion, depending on $S(P)$ only.

Lemma 4.5. Let $N_i$ be a point in the graph of $\sigma = S(P)$. Then $N_i$ is inside a maximal F-block of $R(P)$ if and only if it is a weak point of $S(P)$.

This lemma is proved in Appendix and the rest of the theorem in Appendix □

5. Enumeration of (2-14-3,3-41-2)-avoiding permutations

It follows from Theorem 4.4 that S-permutations of size $n$ are in bijection with Baxter permutations of size $n+1$ in which all maximal ascending F-blocks are increasing (that is, order isomorphic to a permutation of the form 123…m), and all maximal descending F-blocks of size at least 3 are decreasing. A Baxter permutation that does not satisfy these conditions has at least one improper pair.

Definition 5.1. Let $\rho$ be a Baxter permutation. Two points of the diagram of $\rho$ that lie in adjacent rows and columns form an improper pair if they form a descent in a maximal ascending F-block, or an ascent in a maximal descending F-block of size at least 3.

This definition is illustrated in Fig. 23. Observe that a point belongs to at most one improper pair. In particular, a permutation of size $n+1$ has at most $\left\lfloor \frac{n+1}{2} \right\rfloor$ improper pairs.

Figure 23. Improper pairs in maximal F-blocks.
Proposition 5.2. Let 
\[ b_n = \sum_{m=0}^{n} \frac{2}{n(n+1)^2} \binom{n+1}{m} \binom{n+1}{m+1} \binom{n+1}{m+2} \]
be the number of Baxter permutations of size \( n \) (see [15]). The number \( a_n \) of \((2\cdot14\cdot3,3\cdot41\cdot2)\)-avoiding permutations of size \( n \) is 
\[ a_n = \sum_{i=0}^{\lfloor (n+1)/2 \rfloor} (-1)^i \binom{n+1-i}{i} b_{n+1-i}. \]

Proof. We have just explained that \((2\cdot14\cdot3,3\cdot41\cdot2)\)-avoiding permutations of size \( n \) are in bijection with Baxter permutations of size \( n+1 \) having no improper pair. By the inclusion-exclusion principle,
\[ a_n = \sum_{i \geq 0} (-1)^i b_{n+1,i}, \]
where \( b_{n+1,i} \) is the number of Baxter permutations of size \( n+1 \) with \( i \) marked improper pairs. Let \( \rho \) be such a permutation, and contract every marked improper pair into a single (marked) point: this gives a Baxter permutation \( \rho' \) of size \( n+1-i \), with \( i \) marked points.

Observe that if two points of \( \rho \) are in the same maximal F-block, then their images, after contraction, are in the same maximal F-block of \( \rho' \). (The converse is false: the permutation 1342 has two maximal F-blocks and one improper pair (consisting of the values 34). By contracting this pair, one obtains the permutation 132, which is an F-block.)

We claim that each Baxter permutation of size \( n+1-i \) with \( i \) marked points is obtained exactly once in our construction, and that the unique way to expand each marked point into an improper pair is the following:

- if the marked point lies on the diagonal of an ascending maximal F-block (of size \( \geq 1 \)), replace it by a descending pair of adjacent points,
- if the marked point lies on the anti-diagonal of a descending maximal F-block of size \( \geq 2 \), replace it by an ascending pair of adjacent points,
- otherwise, observe that the block has size at least 3; if it is ascending (resp. descending), and the marked point does not lie on the diagonal (resp. anti-diagonal), replace it by an ascending (resp. descending) pair of adjacent points.

Details are left to the reader.

This construction implies that the number of Baxter permutations of size \( n+1 \) having \( i \) marked improper pairs is \( b_{n+1,i} = \binom{n+1-i}{i} b_{n+1-i} \), and the proposition follows. \( \square \)

Remarks
1. Let \( A(t) \) be the generating function of \((2\cdot14\cdot3,3\cdot41\cdot2)\)-avoiding permutations, and let \( B(t) \) be the generating function of (non-empty) Baxter permutations. The above result can be rewritten as
\[ A(t) = \sum_{k \geq 0} t^k (1-t)^{k+1} b_{k+1} = \frac{1}{t} B(t(1-t)). \] 

Observe that \( t(1-t) = s \) if \( t = sC(s) \), where \( C(s) = \frac{1-\sqrt{1-4s}}{2s} \) is the generating function of Catalan numbers. Hence, conversely,
\[ B(s) = sC(s) A(sC(s)). \] 

This suggests that another connection between S- and R-permutations, involving Catalan numbers, exists.

2. The form of \( a_n \) and \( b_n \) implies that \( A(t) \) and \( B(t) \) are D-finite, that is, satisfy a linear differential equation with polynomial coefficients [26, 27]. In fact,
\[ -12t + 6(1-2t) B(t) - 2t \left( -3 + 14t + 8t^2 \right) B'(t) - t^2 (t+1)(8t-1) B''(t) = 0 \]
and

\[ 12(t - 1)(2t - 1)^3 + (104t - 338t^2 + 512t^3 - 294t^4 - 110t^5 + 192t^6 - 48t^7 - 12)A(t) \]
\[ -2t(t - 1)(40t^6 - 128t^5 + 89t^4 + 53t^3 - 88t^2 + 35t - 4)A'(t) - t^2(2t - 1)(8t^2 - 8t + 1)(t^2 - t - 1)(t - 1)^2 A''(t) = 0. \]

This implies that the asymptotic behavior of the numbers \(a_n\) and \(b_n\) can be determined almost automatically (see for instance [18 Sec. VII.9]). For Baxter permutations, it is known [32] that \(b_n \sim 8^n n^{-4}\) (up to a multiplicative constant, which can be determined thanks to standard techniques for the asymptotics of sums [29]). For \(a_n\), we find \(a_n \sim (4 + 2\sqrt{2})^n n^{-4}\).

3. For \(1 \leq n \leq 30\), the number of \((2\text{-}14\text{-}3, 3\text{-}41\text{-}2)\)-avoiding permutations of \([n]\) is given in the following table, which we have sent to the OEIS [31, A214358].

| \(n\) | \(a_n\) | \(b_n\) | \(c_n\) | \(d_n\) | \(e_n\) |
|---|---|---|---|---|---|
| 1 | 374 | 929480 | 4023875702 | 23320440656376 | 16176275797343554 |
| 2 | 1668 | 4803018 | 22364542912 | 135126739754922 | 96390739988587524 |

6. The case of guillotine floorplans

In this section we study the restriction of the map \(S\) to an important family of floorplan called guillotine floorplans [14, 22, 36].

**Definition 6.1.** A floorplan \(P\) is a guillotine floorplan (also called slicing floorplan [24]) if either it consists of just one rectangle, or there is a segment in \(P\) that extends from one side of the boundary to the opposite side, and splits \(P\) into two sub-floorplans that are also guillotine.

The restriction of the map \(R\) to guillotine floorplans induces a bijection between \(R\)-equivalence classes of guillotine floorplans and separable permutations (defined below) [1]. Here, we first characterize permutations that are obtained as \(S\)-permutations of guillotine floorplans, and then enumerate them.

6.1. Guillotine floorplans and separable-by-point permutations

A nonempty permutation \(\sigma\) is separable if it has size 1, or its graph can be split into two nonempty blocks \(H_1\) and \(H_2\), which are themselves separable. Then, either all the points in \(H_1\) are to the SW of all the points of \(H_2\) (then \(\sigma\) is a separable permutation, has an ascending structure), or all the points in \(H_1\) are to the NW of all the points of \(H_2\) (then \(\sigma\) is a separable permutation, has a descending structure). Separable permutations are known to coincide with \((2\text{-}4\text{-}1\text{-}3, 3\text{-}1\text{-}4\text{-}2)\)-avoiding permutations [10]. In particular, they form a subclass of Baxter permutations. The number \(g_n\) of separable permutations of \([n]\) is the \((n - 1)st\) Schröder number [30, A006318], and the associated generating function is:

\[ G(t) := \sum_{n \geq 1} g_n t^n = \frac{1 - t - \sqrt{1 - 6t + t^2}}{2}. \]

**Definition 6.2.** A permutation \(\sigma\) of \([n]\) is separable-by-point if it is empty, or its graph can be split into three blocks \(H_1, H_2, H_3\) such that

- \(H_2\) consists of one point \(N\),
- \(H_1\) and \(H_3\) are themselves separable-by-point (thus, they may be empty), and
- either all the points of \(H_1\) are to the SW of \(N\), and all the points of \(H_3\) are to the NE of \(N\) (then \(\sigma\) has an ascending structure), or all the points of \(H_1\) are to the NW of \(N\) and all the points of \(H_3\) are to the SE of \(N\) (then \(\sigma\) has a descending structure).
The letter \( N \) for the central block refers to the fact that we have denoted by \( N_i \) the point \((i, \sigma(i))\) of an S-permutation \( \sigma \). Observe also that \( N \) necessarily corresponds to a fixed point of \( \sigma \) if \( \sigma \) is ascending, and to a point such that \( \sigma(i) = n + 1 - i \) is \( \sigma \) is descending and has size \( n \).

![Figure 24](image.png)

**Figure 24. Separable-by-point permutations.**

See Fig. 24 for a schematic description and an example of separable-by-point permutations. For \( n \leq 3 \), all permutations are separable-by-point. It is clear that if a nonempty permutation \( \sigma \) is separable-by-point, then it is separable. The permutations 2143 and 3412 are separable, but not separable-by-point. The following result characterizes separable-by-point permutations in terms of forbidden patterns. In particular, it implies that these permutations are S-permutations.

**Proposition 6.3.** Let \( \sigma \) be a permutation of \([n]\). Then \( \sigma \) is separable-by-point if and only if it is \((2-14-3, 3-41-2, 2-4-1-3, 3-1-4-2)\)-avoiding.

**Proof.** Assume that \( \sigma \) is separable-by-point. In particular, \( \sigma \) is separable, and, therefore, it avoids 2-4-1-3 and 3-1-4-2. Assume for the sake of contradiction that \( \sigma \) contains an occurrence of 2-14-3, corresponding to the points \( N_i, N_j, N_{j+1} \) and \( N_k \), and has a minimal size for this property. Then the points forming the pattern must be spread in at least two of the three blocks. This forces \( \sigma \) to have an ascending structure, with \( N_i \) and \( N_j \) in one block, \( N_{j+1} \) and \( N_k \) in the following one (because \( N_j \) and \( N_{j+1} \) are adjacent). But this is impossible as the central block of \( \sigma \) contains a unique point. Similarly one shows that \( \sigma \) avoids 3-41-2.

Conversely, we argue by induction on the size of \( \sigma \). Let \( \sigma \) be a \((2-14-3, 3-41-2, 2-4-1-3, 3-1-4-2)\)-avoiding permutation of \([n]\). For \( n \leq 3 \) there is nothing to prove. Let \( n \geq 4 \). Since \( \sigma \) is \((2-4-1-3, 3-1-4-2)\)-avoiding, it is separable. Assume without loss of generality that \( \sigma \) (as a separable permutation) has an ascending structure: the first block is \([1, i] \times [1, i]\), the second block is \([i+1, n] \times [i+1, n]\) where \( 1 \leq i < n \). If \( \sigma(i) \neq i \) and \( \sigma(i+1) = i+1 \), then \( \sigma^{-1}(i), i, i+1, \sigma^{-1}(i+1) \) form a forbidden pattern 2-14-3. Thus, \( \sigma(i) = i \) or \( \sigma(i+1) = i+1 \), and one obtains a three-block decomposition of \( \sigma \) by choosing for the central block \( N \) one of these two fixed points. The remaining two blocks avoid all four patterns, and, therefore, are separable-by-point themselves by the induction hypothesis. It follows that \( \sigma \) is separable-by-point.

**Theorem 6.4.** A floorplan \( P \) is a guillotine floorplan if and only if \( S(P) \) is separable-by-point.

**Proof.** Let \( P \) be a guillotine floorplan. We argue by induction on the size of \( P \). If \( P \) consists of a single rectangle, then \( S(P) \) is the empty permutation, and is separable-by-point. Otherwise, consider a segment that splits \( P \) into two rectangles. Assume that this segment is \( I_i \) (that is, the \( i \)th segment in the \( \prec \) order) and that it is vertical. All the segments to the left (respectively, right) of \( I_i \) come before (respectively, after) \( I_i \) in the \( \prec \) and \( \preceq \) orders. Consequently:

- \( I_i \) is also the \( i \)th segment in the \( \preceq \) order, so that \( N_i = (i, i) \),
- by Observation 6.3 all the points of the graph of \( \sigma \) that correspond to segments located to the left (respectively, right) of \( I_i \) are to the SW (respectively, NE) of \( N_i \).
Thus, we have three blocks \( H_1, H_2 \) and \( H_3 \) with an ascending structure. The blocks \( H_1 \) and \( H_3 \) are the S-permutations of the two parts of \( P \), which are themselves guillotine: by the induction hypothesis, \( H_1 \) and \( H_3 \) are separable-by-point. Thus \( S(P) \) is separable-by-point with an ascending structure.

Similarly, if \( I_i \) is horizontal, we obtain a separable-by-point permutation with a descending structure.

Conversely, assume that \( \sigma := S(P) \) is separable-by-point. We will prove by induction on \( n \) that \( P \) is a guillotine floorplan.

The claim is clear for \( n = 1 \). For \( n > 1 \), assume without loss of generality that \( \sigma \) has an ascending structure. Let \( H_2 = \{(i, i)\} \) be the second block in a decomposition of \( \sigma \). Then for all \( j < i \), we have \( I_j \prec I_i \), and for all \( j > i \), we have \( I_i \prec I_j \). Therefore, if \( I_i \) is vertical, it has no below- or above-neighbors, and thus extends from the lower to the upper side of the boundary. The two sub-floorplans of \( P \) correspond respectively to the blocks \( H_1 \) and \( H_3 \); hence they are guillotine by the induction hypothesis. Suppose now that \( I_i \) is horizontal. Then we have \( \sigma(i - 1) = i - 1 \) (if \( i > 1 \)) and \( \sigma(i + 1) = i + 1 \) (if \( i < n \)), since otherwise \( I_i \) has several left-neighbors or several right-neighbors (Observation 3.3), which is never the case for a horizontal segment. Assume without loss of generality that \( i > 1 \). Then another block decomposition of \( \sigma \) is obtained with the central block \( H'_2 = \{(i - 1, i - 1)\} \), corresponding to the vertical segment \( I_{i-1} \). The previous argument then shows that \( P \) is guillotine. \( \square \)

### 6.2. Enumeration

In this section we enumerate S-equivalence classes of guillotine floorplans, or equivalently, separable-by-point permutations.

**Proposition 6.5.** For \( n \geq 1 \), let \( g_n \) be the number of separable permutations of size \( n \), and let \( G(t) \) the associated generating function, given by \([3] \). The number \( h_n \) of separable-by-point permutations of size \( n \) is

\[
h_n = \sum_{i=0}^{\lfloor (n+1)/2 \rfloor} (-1)^i \binom{n+1-i}{i} g_{n+1-i}.
\]

Equivalently, the generating function of separable-by-point permutations is

\[
H(t) = \sum_{n \geq 0} h_n t^n = \sum_{n \geq 0} t^n (1-t)^{n+1} g_{n+1} = \frac{1}{t} G(t(1-t)) = \frac{1-t+t^2-\sqrt{1-6t+7t^2-2t^3+t^4}}{2t}.
\]

**Proof.** Recall that the R-permutations associated with guillotine floorplans are the separable permutations, and return to the proof of Proposition 6.4. The contraction/expansion of points used in this proof preserves separability, so that we can apply the same argument, which yields directly the proposition. \( \square \)

### Remarks

1. The first values are 1, 2, 6, 20, 70, 254, 948, 3618, 14058, 55432. This sequence \([30] \ A078482 \) also enumerates (2-4-3-1, 3-2-4-1, 2-4-1-3, 3-1-4-2)-avoiding permutations (or permutations sortable by a stack of queues), as found by Atkinson and Stitt \([25] \ Thm. 17 \).
2. Using the *transfer theorems* from \([15] \ Sec. VI.4 \), we can find the asymptotic behavior of the numbers \( h_n \):

\[
h_n \sim \left( \frac{2}{1-\sqrt{8\sqrt{2}-11}} \right)^n n^{-3/2},
\]

up to a multiplicative constant.

3. A generalization of Proposition 6.5 to \( d \)-dimensional guillotine partitions is presented in \([4] \).

### 7. Final remarks

We have shown that many analogies exist between R- and S-equivalence. However, there also seems to be one important difference. Looking at Fig. 1 suggests that one can transform a floorplan into an R-equivalent one by some continuous deformation. In other words, R-equivalence classes appear as geometric planar...
objects. This is confirmed by the papers [9, 17, 20], which show that bipolar orientations of planar maps provide a convenient geometric description of R-equivalence classes of floorplans. However, S-equivalence is a coarser relation, and two S-equivalent floorplans may look rather different (Figs. 11 and 21). It would be interesting to find a class of geometric objects that captures the notion of S-equivalence classes, as bipolar orientations do for R-equivalence classes.

In Section 5 we have established a simple enumerative connection, involving Catalan numbers, between Baxter permutations and (2-14-3,3,41-2)-avoiding permutations. Is there a direct combinatorial proof of (2), not based on Theorem 4.4 (the proof of which is rather heavy)? Recall that \( C(s) \) is related to pattern avoiding permutations, since it counts \( \tau \)-avoiding permutations, for any pattern \( \tau \) of size 3.

We conclude with a summary of the enumerative results obtained in [1] for R-equivalence classes and in the present paper for S-equivalence classes.

Acknowledgements. We thank Éric Fusy for interesting discussions on the genesis of Baxter permutations, and also for discovering, with Nicolas Bonichon, a mistake in an earlier (non-)proof of Proposition 5.2. We also thank Mathilde Bouvel for her help in proving that the reverse bijection \( S^{-1} \) can be implemented in linear time. Finally, we acknowledge interesting comments from the referees of the first version of the paper.

Appendix A. Proof of Proposition 3.12, Paragraph D

We prove that, given a permutation \( \sigma \), (any) floorplan \( P \) obtained by the construction described in Paragraph A-B of the proof satisfies \( S(P) = \sigma \).

In order to prove this claim, we will show that for all \( 1 \leq i < n \), the segment \( K_{i+1} \) is the immediate successor of \( K_i \) in the \( \prec \) order, and that \( K_{\sigma^{-1}(i+1)} \) is the immediate successor of \( K_{\sigma^{-1}(i)} \) in the \( \prec \) order.

Let us first prove that the first statement implies the second. Let \( \sigma' \) be obtained by applying a quarter-turn rotation \( \rho \) to \( \sigma \) in counterclockwise direction. Let us denote by \( K'_i \) the segment of \( P' = \rho(P) \) containing the point \((i, \sigma'(i))\). By Observation 3.13 the floorplan \( P' \) is associated with \( \sigma' \) by our construction. That is, \( \rho(K_{\sigma^{-1}(i)}) = K'_{\sigma^{-1}(i)} \). By assumption, \( K'_{n+1-i} = \rho(K_{\sigma^{-1}(i)}) \) follows \( K'_{n-i} = \rho(K_{\sigma^{-1}(i+1)}) \) for the \( \prec \) order in \( P' \). Applying the quarter turn clockwise rotation \( \rho^{-1} \) and the second remark following Proposition 2.12 this means that \( K_{\sigma^{-1}(i+1)} \) follows \( K_{\sigma^{-1}(i)} \) for the \( \prec \) order in \( P \).

Thus we only need to prove that \( K_{i+1} \) is the immediate successor of \( K_i \) in the \( \prec \) order. By Observation 2.10 the immediate successor of a horizontal (respectively, vertical) segment \( I \) in the \( \prec \) order is \( R(I) \), \( LVB(I) \) or \( LHB(I) \) (respectively, \( B(I) \), \( UHR(I) \) or \( UVR(I) \)) depending on the existence of these segments and the type of joins between them.

There are 8 cases to consider, depending on whether \( \sigma(i) < \sigma(i+1) \) or \( \sigma(i) > \sigma(i+1) \), and on the directions of \( K_i \) and \( K_{i+1} \).

Case 1: \( \sigma(i) < \sigma(i+1) \), \( K_i \) and \( K_{i+1} \) are vertical.

Assume that \( N_j \) bounds \( K_i \) from above. Then, as shown in Paragraph C.1 above, \( K_j \) is horizontal; furthermore, \( K_i \) and \( K_j \) have a \( \tau \) join at the point \((i, \sigma(j))\). In particular, the rightmost point of \( K_j \) has abscissa at least \( i+1 \).

If \( \sigma(j) < \sigma(i+1) \), then \( N_{i+1} \) bounds \( K_j \) from the right. There is a \( \tau \) join of \( K_j \) and \( K_{i+1} \) at the point \((i+1, \sigma(j))\) (Fig. 25.1).

If \( \sigma(j) > \sigma(i+1) \), then \( N_j \) bounds \( K_{i+1} \) from above and there is a \( \tau \) join of \( K_j \) and \( K_{i+1} \) (Fig. 25.2).

If \( N_j \) does not exist and \( K_i \) reaches the upper side of the boundary, then no point can bound \( K_{i+1} \) from above, and, thus, \( K_{i+1} \) reaches the boundary as well (Fig. 25.3).

In all these cases, it is readily seen that \( K_{i+1} \) is \( UVR(K_i) \).

By Observation 2.10 \( UVR(K_i) \) is the successor of \( K_i \), unless \( UHR(K_i) \) does not exist, \( B(K_i) := K_p \) exists and its join with \( UVR(K_i) \) is of type \( \tau \) (Fig. 25.4)). But this would mean that \( p < i \), and the positions of \( N_i \) and \( N_p \) would then contradict Observation 3.14.

![Figure 25](image-url)

**Figure 25.** The first case.

Case 2: \( \sigma(i) < \sigma(i+1) \), \( K_i \) is vertical and \( K_{i+1} \) is horizontal.

---

\(^{10}\)This notation is defined before Observation 2.10
The point \( N_i \) bounds \( K_{i+1} \) from the left. Therefore, there is a \( \perp \) join of \( K_i \) and \( K_{i+1} \) at the point \( (i, \sigma(i+1)) \), and \( K_{i+1} \) is a horizontal right-neighbor of \( K_i \). Moreover, if \( K_k \) is another horizontal right-neighbor of \( K_i \), then \( \sigma(k) < \sigma(i+1) \): otherwise \( N_i \) cannot be a SW-neighbor of \( N_k \) (Fig. 26 left). Therefore, \( K_{i+1} = \text{UHR}(K_i) \).

By Observation 2.10, UHR\((K_i)\) is the successor of \( K_i \), unless UVR\((K_i) : = K_p \) exists (Fig. 26 right). If this were the case, \( K_p \) and \( K_{i+1} \) would have a \( \perp \) join, and the position of \( N_{i+1} \) and \( N_p \) would then be incompatible with Observation 3.14.

![Figure 26. The second case.](image)

**Case 3:** \( \sigma(i) < \sigma(i+1) \), \( K_i \) is horizontal and \( K_{i+1} \) is vertical.

We claim that this case follows from the previous one. Let \( \sigma' \) be obtained by applying a half-turn rotation \( \rho \) to (the graph of) \( \sigma \). By Observation 2.10, the floorplan \( P' = \rho(P) \) is associated with \( \sigma' \). The points and segments \( \rho(N_i), \rho(N_{i+1}), \rho(K_i), \rho(K_{i+1}) \) in \( P' \) are in the configuration described by Case 2, with \( \rho(N_{i+1}) \) to the left of \( \rho(N_i) \). Consequently, \( \rho(N_i) \) is the successor of \( \rho(N_{i+1}) \) in the \( \bowtie \) order in \( P' \). By the first remark that follows Proposition 2.12, \( N_{i+1} \) is the successor of \( N_i \) in the \( \bowtie \) order in \( P \).

**Case 4:** \( \sigma(i) < \sigma(i+1) \), \( K_i \) and \( K_{i+1} \) are horizontal.

If this case, \( N_i \) bounds \( K_{i+1} \) from the left. Therefore, \( K_i \) must be vertical (see Paragraph C.1 above). Hence, this case is impossible.

**Case 5:** \( \sigma(i) > \sigma(i+1) \), \( K_i \) and \( K_{i+1} \) are vertical.

Since \( K_{i+1} \) is vertical, \( N_{i+1} \) has at most one NW-neighbor, which is then \( N_i \). By Paragraph C.1 above, \( K_i \) is then horizontal. Thus this case is impossible.

**Case 6:** \( \sigma(i) > \sigma(i+1) \), \( K_i \) is vertical and \( K_{i+1} \) is horizontal.

Since the segment \( K_i \) is vertical, the point \( N_i \) has at most one SE-neighbor, which is then \( N_{i+1} \). Therefore, \( N_{i+1} \) bounds \( K_i \) from below, and there is a \( \perp \) join of \( K_i \) and \( K_{i+1} \) at the point \( (i, \sigma(i+1)) \). In particular, \( K_{i+1} = B(K_i) \).

By Observation 2.10 \( B(K_i) \) is the successor of \( K_i \), unless UHR\((K_i) : = K_k \) exists (Case (3.2) in Fig. 8), or UHR\((K_i) \) does not exist, but UVR\((K_i) : = K_p \) exists and forms with \( B(K_i) \) a \( \perp \) join (Case (4.1) in Fig. 8). In the former case, \( K_k \) reaches \( K_i \) and thus is bounded by \( N_i \) on the left, but then \( N_i \) and \( N_{i+1} \) are two SW-neighbors of \( N_i \), and \( K_k \) cannot be horizontal. In the latter case, \( K_p \) and \( K_{i+1} \) would form a \( \perp \) join, and the positions of \( N_p \) and \( N_{i+1} \) would contradict Observation 3.14.

**Case 7:** \( \sigma(i) > \sigma(i+1) \), \( K_i \) is horizontal and \( K_{i+1} \) is vertical.

This case follows from Case 6 by the symmetry argument already used in Case 3.

**Case 8:** \( \sigma(i) > \sigma(i+1) \), \( K_i \) and \( K_{i+1} \) are horizontal.

The point that bounds \( K_i \) from the right, if it exists, lies to the NE of \( N_{i+1} \). Thus the abscissa of the rightmost point of \( K_i \) is greater than or equal to the abscissa of the rightmost point of \( K_{i+1} \).
We will show that \( K_{i+1} = \text{LHB}(K_i) \). Once this is proved, Observation 2.10 implies that \( \text{LHB}(K_i) \) is the successor of \( K_i \), unless \( \text{LVB}(K_i) \) does not exist, but \( R(K_i) \) exists and forms with \( K_{i+1} \) a \( \perp \) join (Case (4.2) in Fig. 5). But this would mean that \( K_{i+1} \) ends further to the right than \( K_i \), which we have just proved to be impossible.

So let us prove that \( K_{i+1} = \text{LHB}(K_i) \). We assume that \( K_i \) does not reach the left side of the boundary, and that \( K_{i+1} \) does not reach the right side of the boundary (the other cases are proven similarly). Let \( N_k \) be the point that bounds \( K_i \) from the left, and let \( N_m \) be the point that bounds \( K_{i+1} \) from the right.

Consider \( A \), the leftmost rectangle whose upper side is contained in \( K_i \). The left side of \( A \) is clearly contained in \( K_k \). We claim that the lower side of \( A \) is contained in \( K_{i+1} \), and that the right side of \( A \) is contained in \( K_m \). Note that this implies \( K_{i+1} = \text{LHB}(K_i) \).

Let \( K_p \) (respectively, \( K_q \)) be the segment that contains the lower (respectively, right) side of \( A \). Clearly, \( q > k \). If \( q < i \), then \( K_q \) is a vertical below-neighbor of \( K_i \), and the positions of \( N_q \) and \( N_i \) contradict Observation 3.14. Therefore, \( q > i + 1 \).

Consider now the segment \( K_p \). Clearly, \( \sigma(p) \geq \sigma(i + 1) \). One cannot have \( p > i + 1 \): otherwise \( N_{i+1} \) (or a point located to the right of \( N_{i+1} \)) would bound \( K_p \) from the left, and \( K_p \) would not reach \( K_k \). One cannot have either \( p < i \): otherwise \( N_i \) (or a point located to the left of \( N_i \)) would bound \( K_p \) from the right, and \( K_p \) would not reach \( K_q \). Since \( p \neq i \), we have proved that \( p = i + 1 \), and \( K_k \) is bounded by \( N_{i+1} \) from below.

Finally, \( K_q \) coincides with \( K_{m_3} \): otherwise, \( q < m \), and \( K_q \) is a vertical above-neighbor of \( K_{i+1} \); however, in this case \( N_q \) would bound \( K_{i+1} \) from the right, and \( K_{i+1} \) would not reach \( K_m \).

We have thus proved that \( K_{i+1} = \text{LHB}(K_i) \), and this concludes the study of this final case, and the proof of Proposition 3.12.

**Appendix B. Proof of Lemma 4.5**

Let \( N_i = (i,j) \) be inside a maximal F-block of \( R(P) \). Assume for the sake of contradiction that \( N_i \) is strong, and for instance, has several NE-neighbors. Let \( N_k \) be the leftmost NE-neighbor of \( N_i \), and let \( N_\ell \) be the lowest NE-neighbor of \( N_i \). If \( k > i + 1 \), then \( \sigma(k - 1) < \sigma(i) \), and, therefore, \( i, k - 1, k, \ell \) form a forbidden pattern 2-14-3. Thus \( k = i + 1 \). Symmetrically, \( \sigma(\ell) = j + 1 \) (Fig. 27). Note also that \( \sigma(i + 1) > j + 1 \) and \( \sigma^{-1}(j + 1) > i + 1 \). Since the points of \( S(P) \) inside an F-block are either on the diagonal or the anti-diagonal of this block, \( N_i \) is the highest (and rightmost) point of \( S(P) \) inside the maximal F-block that contains it, and this F-block is of ascending type. In particular, either \( \rho(i + 1) = j + 1 \), or \( \rho(i) = j + 1 \) and \( \rho(i + 1) = j \).

Since \( \rho(i + 1) \leq j + 1 \) and \( \sigma(i + 1) \geq j + 2 \), then \( \rho(i + 2) \geq j + 3 \) (Theorem 4.2). Symmetrically, \( \rho^{-1}(j + 2) \geq i + 3 \). But then the position of the point \( \rho^{-1}(j + 2), j + 2 \) is not compatible with the position of \( N_{i+1} \): by Theorem 4.2 there cannot be a point of \( \rho \) located to the right of \( \rho(i + 2) \) and in the rows between those of \( \rho(i + 1) \) and \( N_{i+1} \). Hence \( N_i \) cannot have several NE-neighbors. Symmetric statements hold for the other directions, and \( N_i \) is a weak point.

Now let \( N_i = (i,j) \) be a point of the graph of \( \sigma \), not inside a maximal F-block. Assume without loss of generality that \( \rho \) has an ascent at \( i \): \( \rho(i) \leq j < \rho(i + 1) \) and (by Theorem 4.2) \( \rho^{-1}(j) \leq i < \rho^{-1}(j + 1) \). We shall show that \( N_i \) has several SW-neighbors or several NE-neighbors. We denote \( M_i = (i, \rho(i)) \).

First, if \( \rho(i) = j \) and \( \rho(i + 1) = j + 1 \), then \( M_i \) and \( M_{i+1} \) form an F-block, and \( N_i \) is inside this block. Therefore, either \( \rho(i) \neq j \) or \( \rho(i + 1) \neq j + 1 \), and we may assume without loss of generality that \( \rho(i) \neq j \); hence \( \rho(i) < j \) and \( \rho^{-1}(j) < i \). Then it follows from the definition of Baxter permutations that \( \rho(i - 1) \leq j \) (otherwise, there is an occurrence of 2-41-3 at positions \( \rho^{-1}(j), i - 1, i \), \( \rho^{-1}(j + 1) \)). Consequently, we have \( \sigma(i - 1) \leq j - 1 \). Symmetrically, \( \rho^{-1}(j - 1) \leq i \) and \( \sigma^{-1}(j - 1) \leq i - 1 \). There are two possibilities: either \( \sigma(i - 1) < j - 1 \) and \( \sigma^{-1}(j - 1) < i - 1 \), or \( \sigma(i - 1) = j - 1 \). In the former case, \( N_{i-1} \) and \( N_{\sigma^{-1}(j-1)} \) are two SW-neighbors of \( N_i \), and we have proved that \( N_i \) is strong. Let us go on with the latter case, where \( \rho(i - 1) = j \) and \( \rho(i) = j - 1 \).

If \( \rho(i + 1) = j + 1 \), then \( M_{i-1}, M_i \) and \( M_{i+1} \) form an F-block, and \( N_i \) is inside this block, which contradicts our initial assumption. Otherwise, \( \rho(i + 1) \neq j + 1 \), and an argument similar to the one developed just above shows that either \( N_{i+1} \) and \( N_{\sigma^{-1}(j+1)} \) are two NW-neighbors of \( N_i \), or \( \rho(i + 1) = j + 2 \) and \( \rho(i + 2) = j + 1 \).
In the latter case, $M_{i-1}$, $M_i$, $M_{i+1}$ and $M_{i+2}$ form an F-block containing $N_i$, which contradicts our initial assumption.

**Appendix C. Proof of Theorem 4.4, the “only if” direction**

Let $\sigma$ be a $(214-3,341-2)$-avoiding permutation of size $n$. Let $B$ be the set of Baxter permutations whose S-permutation (described by Theorem 1.2) is $\sigma$. Lemma 4.5 determines which points of the graph of $\sigma$ are inside an F-block. These points are organized along the diagonal or anti-diagonal of their blocks. It follows that the location of all non-trivial F-blocks in the graph of $\rho$, for $\rho \in B$, and their type (ascending or descending, for blocks of size at least 3), are also determined uniquely. It remains to show that the location of the trivial F-blocks (that is, F-blocks of size 1) is also determined by $\sigma$.

Assume for the sake of contradiction that $B$ contains two distinct permutations $\rho_1$ and $\rho_2$. Let $i$ be the abscissa of the leftmost trivial F-block that is not at the same ordinate in the graphs of $\rho_1$ and $\rho_2$. Denote $j = \sigma(i)$. By symmetry, we only have to consider two cases: (1) $\rho_1(i) < \rho_2(i) \leq j$; (2) $\rho_1(i) \leq j < \rho_2(i)$.

In the first case (Fig. 28), denote $k = \rho_2(i)$. Consider $\rho_1^{-1}(k)$. By assumption, $\rho_1^{-1}(k) \neq i$. Since $\rho_1(i) < k$ and $\sigma(i) = j \geq k$, we have $\rho_1^{-1}(k) < i$ by Theorem 1.2. However, this is impossible since the F-structures of $\rho_1$ and $\rho_2$ coincide to the left of the $i$th column.

Consider the second case, $\rho_1(i) \leq j < \rho_2(i)$ (Fig. 29). Since $\rho_1(i) \leq j$ and $\sigma(i) = j$, the areas $[1,i] \times \{j+1\}$ and $[i+1,n] \times \{j\}$ are empty in the graph of $\rho_1$. Similarly, since $\rho_2(i) > j+1$, the areas $[1,i] \times \{j\}$ and $[i+1,n] \times \{j+1\}$ are empty in the graph of $\rho_2$. Since the F-structures of $\rho_1$ and $\rho_2$ coincide in $[1,i-1] \times [1,n]$, the areas $[1,i-1] \times \{j\} \times \{j+1\}$ are empty in the graphs of both permutations. Given that rows cannot be empty, this forces $\rho_1(i) = j$ and $\rho_2(i) = j+1$ (Fig. 30).

Assume without loss of generality that $\sigma(i+1) < j$. Since $\rho_1(i) = j$ and $\sigma(i) = j$, we have, by Theorem 1.2, $\rho_1(i+1) \geq j+1$. In fact $\rho_1(i+1) > j+1$ since otherwise the point $(i,\rho_1(i))$ would not form a trivial F-block. Now, since $\sigma(i+1) < j$, the area $[i+2,n] \times \{j+1\}$ is empty in the graph of $\rho_1$. This area is also empty in the graph of $\rho_2$, since $\rho_2(i) = j+1$. Since the F-structures of $\rho_1$ and $\rho_2$ coincide in $[1,i-1] \times [1,n]$, the area $[1,i-1] \times \{j+1\}$ is also empty in the graph of $\rho_1$. Since $\rho_1(i) = j$ and $\rho_1(i+1) > j+1$, we have a contradiction: the whole row $j+1$ is empty in the graph of $\rho_1$.

Thus, we have proved that all $\rho \in B$ have the same F-structure.
Figure 28. Proof of Theorem 4.4: the case $\rho_1(i) < \rho_2(i) \leq j$. The shaded areas contain no point.

Figure 29. Proof of Theorem 4.4: the case $\rho_1(i) \leq j < \rho_2(i)$.

Figure 30. Proof of Theorem 4.4: the case $\rho_1(i) \leq j < \rho_2(i)$, continued.
