Abstract

The characteristics of CO₂ adsorption sites on a nitrogen-doped graphite model system (N-HOPG) were investigated by X-ray photoelectron and absorption spectroscopy and infrared reflection absorption spectroscopy. Adsorbed CO₂ was observed lying flat on N-HOPG, stabilized by a charge transfer from the substrate. This demonstrated that Lewis base sites were formed by the incorporation of nitrogen via low-energy nitrogen-ion sputtering. The possible roles of twofold coordinated pyridinic N and threefold coordinated valley N (graphitic N) sites in Lewis base site formation on N-HOPG are discussed. The presence of these nitrogen species focused on the appropriate interaction strength of CO₂ indicates the potential to fine-tune the Lewis basicity of carbon-based catalysts.

Keywords: CO₂ adsorption, Nitrogen-doped carbon, Lewis basicity, X-ray photoelectron spectroscopy, X-ray absorption spectroscopy, Infrared reflection absorption spectroscopy

Background

The problem of capturing and storing of CO₂ as a primary greenhouse gas must be solved to alleviate global warming. Captured CO₂ is typically utilized as a simple carbon-containing feedstock (C1) for generating industrially relevant organic molecules [1]. Numerous porous solid adsorbates such as zeolites [2], metal-organic frameworks [3], and mesoporous carbons [4, 5] have been proposed for the effective capture and processing of CO₂. Some research groups have reported that nitrogen-doped carbon materials interact more effectively with CO₂ than inactive carbon materials do [4–8]. Furthermore, they are also expected as promising electrocatalysts for CO₂ and oxygen reduction reaction [8, 9]. Accordingly, the nitrogen doping of carbon materials is expected to be an effective process to enhance CO₂ storage capacity and CO₂ reactivity. CO₂ is a weak Lewis acid with an electropositive carbon atom that can detect nitrogen-doping-induced basic sites on carbon materials [10, 11]; this detection is classified as a Lewis acid/base reaction.

For practical uses of CO₂ adsorbents or catalysts, it is important to balance effective capturing and reduction reaction. A theoretical CO₂ adsorption mechanism has been proposed for the catalysts and capturing materials currently in use. For example, hydrogen bonds may form between the surface functional groups and the oxygen atoms of a CO₂ molecule [6]; pyridinic nitrogen species may act as anchors for CO₂ capture [7]; lone-pair electrons of pyridinic nitrogen may be active for CO₂ reduction [8]. However, detailed experimental information regarding the chemical state and geometry of adsorbed CO₂ on nitrogen-doped carbon materials is scarce, which hinders the design of effective, highly selective CO₂ capturing materials and catalysts for CO₂ reduction.

In this study, we investigated the adsorption properties of CO₂ on nitrogen-doped graphite (N-HOPG), synthesized using low-energy nitrogen-ion sputtering, using X-ray photoelectron spectroscopy (XPS), angle-resolved X-ray absorption spectroscopy (XAS), and infrared reflection-absorption spectroscopy (IRAS). Using the highly graphitized model N-HOPG with selective nitrogen doping, we discuss the possible contribution of nitrogen components to the formation of Lewis base sites on N-HOPG.
**Methods**

A cleaved highly oriented pyrolytic graphite (HOPG, PGcSTM, Panasonic Inc.) plate was annealed at 1000 K for 30 min in an ultra-high vacuum (UHV) (<5 × 10⁻⁷ Pa), sputtered with 8 × 10¹³ nitrogen ions cm⁻² at 200 eV (equivalent to 2% nitrogen relative to the surface carbon atoms) at 300 K using an ion gun (OMI-0730, Omegatron Inc.), and annealed again at 1000 K for 1 h for surface cleaning [12].

XPS measurements were performed at BL27SU in a third-generation synchrotron radiation facility Spring-8 using a photoelectron analyzer (PHOIBOS 150, SPECS). The typical base pressures for the measurement and preparation chambers were 4 × 10⁻⁸ and 3 × 10⁻⁷ Pa, respectively. The incident photon energy and the photoemission angle were 850 eV and 45°, respectively. The total energy resolution of the XPS was 230 meV. Samples were scanned with the incident photon beam at a rate of 0.4 μm s⁻¹ to reduce the radiation damage to the adsorbed molecules. The binding energies were calibrated using the Au 4f 7/2 (binding energy = 84.0 eV) peak of an evaporated gold as a reference. The N 1s spectra were fitted with the Voigt function (1.2 and 0.25 eV Gaussian and Lorentzian widths, respectively) as well as background subtraction using the Shirley method. The normalized intensity of each peak was calculated by multiplying the integrated intensity and the cross section of each element. N/C and O/C ratios were calculated by dividing the normalized intensities of the N 1s and O 1s spectra by that of C 1s spectrum, respectively. The surface nitrogen density was estimated by an assumption that nitrogen atoms are located only at the first graphite layer of HOPG. When we take into account the attenuation of photoelectrons in the bulk region, the contribution to the photoelectron from the first graphite layer of HOPG. When we take into account the attenuation of photoelectrons in the bulk region, the contribution to the photoelectron from the first graphite layer is calculated by 1−exp(−d/λcosθ) where d is the interlayer distance, λ is the inelastic mean free path, and θ is the photoemission angle. In the present case for the C 1s XPS spectrum of graphite, this value is estimated to be 0.33 where d is 3.354 Å, λ is 11.77 Å [13] at 561 eV of kinetic energy which is obtained by subtracting the core level of C 1s (~284 eV) and work function of graphite (4.6 eV) [14] from the incident photon energy hv = 850 eV, and θ is 45°. Therefore, the surface nitrogen and the adsorbed CO₂ densities (ML) are estimated by dividing the normalized intensities of the N 1s and O 1s XPS spectra by one third of that of the C 1s spectrum, respectively. Here, the number of the 1 ML nitrogen atoms is defined as that of the carbon atoms at the first graphite layer (3.82 × 10¹⁵ atoms cm⁻²). The number of the adsorbed 1 ML CO₂ molecules is also defined as that of the carbon atoms at the first graphite layer and to get the number of CO₂ molecules, the estimated value from O 1s XPS should be divided by 2 since CO₂ is composed of two oxygen atoms and one carbon atom.

N 1s and O 1s XAS spectra were measured by the partial electron yield (PEY) mode at BL27SU. The XAS spectra were collected by setting the angle θ between the incident X-ray beam axis and the surface normal to 0°, 45°, and 70°. The energy resolution of XAS had a lower limit below 100 meV.

The N-HOPG was annealed at 1000 K for 30 min in the preparation chamber to remove the initially adsorbed gas before the XPS and XAS measurements were performed. The sample was exposed to CO₂ at 300 K for 2500 s at 5.3 × 10⁻⁸ Pa, corresponding to 10,000 L in volume.

IRAS measurements were performed in grazing-angle reflection geometry both before and after CO₂ adsorption at 300 K to investigate the configuration of the adsorbed CO₂. In order to estimate the amount of the adsorbed CO₂ temperature-programmed desorption (TPD) was performed between 300 and 700 K, with CO₂ adsorption at 300 K. Both the IRAS and TPD experiments were performed in the same UHV (3 × 10⁻⁸ Pa) chamber.

**Results and Discussion**

Figure 1a shows the C 1s XPS spectra of HOPG and N-HOPG. The spectral intensities are normalized to the peak areas. The nitrogen ion sputtering causes the C 1s peak to broaden and introduces the C=N bond peak at 285.6 eV [15]. Figure 1b shows the N 1s XPS spectrum of N-HOPG. The N/C ratio and surface nitrogen density are calculated to be 0.0042 and 0.013 ML, respectively. The spectrum is fitted with four Voigt functions corresponding to each nitrogen component, denoted as pyridinic N (398.0 eV), cyanide N (399.9 eV), center N (401.0 eV), and valley N (401.9 eV). The terminology of the nitrogen components used hereafter is represented in Fig. 1c. Pyridinic N is connected to two carbon atoms and exists either at graphite edges or in the basal plane of graphite with a monovacancy [16]. Cyanide N has triple bonds between the nitrogen and carbon atoms [17]. Both center N and valley N are graphitic N connected to three carbon atoms, existing in the graphite basal plane, and at graphite zigzag edges or vacancy sites, respectively [18, 19]. The detailed peak assignment of each component was discussed in our previous report [12]. The estimated amount of each nitrogen component from the fitting results is summarized in Table 1; center N is the most prevalent, followed by valley N and pyridinic N.

Figure 2a shows the estimated area intensity of the mass 44 (CO₂) peak as a function of CO₂ exposure obtained by the TPD measurements. The saturation amount of adsorbed CO₂ on N-HOPG is near 10,000 L;
this amount was used for the XPS and XAS measurements. A clear CO₂ desorption peak is observed between 320 and 400 K, which approaches the temperature of CO₂ desorption for nitrogen-doped graphite model catalysts [20]. In addition, the amount of the adsorbed CO₂ on N-HOPG is almost constant when 5000 L CO₂ exposure was performed twice as shown in Fig. 2a, which indicates CO₂ adsorption is reversible without poisoning. In contrast, only physisorbed CO₂ was reported on HOPG, which desorbed at 83 K with the desorption energy of 20 kJ mol⁻¹ [21]. Therefore, nitrogen doping forms CO₂ adsorption sites at 300 K on the HOPG surface. Figure 2b, c shows O 1s XPS spectra of HOPG and N-HOPG before and after CO₂ adsorption, respectively. A very small amount of oxygen species (O/C = 0.04 at.%) exists in N-HOPG before CO₂ adsorption, as shown in Fig. 2c, which are not fully removed by annealing at 1000 K for 30 min. The difference spectrum in Fig. 2c shows an O 1s peak centered at approximately 533 eV caused by CO₂ adsorption on N-HOPG. The extracted O/C ratio and the adsorbed CO₂ density are calculated to be 0.00023 and 0.00035 ML, respectively, based on the procedure described in the “Methods” section. However, the difference spectrum in Fig. 2b of HOPG shows no peak related to adsorbed CO₂. Table 2 summarizes the O 1s binding energies for physisorbed and chemisorbed CO₂ on various substrates [22–27]; for physisorbed CO₂, the binding energy is distributed from 534.0 to 535.8 eV, while for chemisorbed CO₂, it ranges from 530.6 to 533 eV. The observed CO₂ binding energy at 533 eV on N-HOPG is below that of physisorbed CO₂ but within the range of chemisorption. The interaction strength of CO₂ directly estimates the degree of Lewis basicity of the N-HOPG substrate. To determine the origin of this binding energy, we discuss the electronic structure of CO₂ as presented by a Walsh diagram in Fig. 2d [28]. The lowest unoccupied molecular orbital (LUMO) of 2πu is degenerated in the linear configuration, while it splits into 2b₁ (perpendicular to the CO₂

Fig. 1 XPS spectra of HOPG and N-HOPG before CO₂ adsorption. a C 1s XPS, b N 1s XPS. c A schematic of each nitrogen configuration in N-HOPG. Hydrogen, carbon, and nitrogen atoms are represented by white, black, and blue balls, respectively.
plane) and 6a1 (parallel to the CO2 plane) orbitals in the bent configuration. In particular, the energy position of 6a1 orbital sharply decreases upon bending. In the bent configuration, this low-energy 6a1 orbital is occupied by electrons charge-transferred from the substrate and stabilizes the adsorbed CO2 molecules on N-HOPG. Thus, the charge transfer from the substrate to the 6a1 orbital in the bent configuration weakens the strength of CO bonds, causing the O 1s core level shift of CO2 to the lower binding energy at approximately 533 eV. This result also provides evidence for the presence of Lewis base sites in the graphite system caused by the doped nitrogen.

In order to reveal the orientation of the adsorbed CO2 on N-HOPG, angle-resolved XAS was performed. Figure 3a shows the O 1s XAS spectra of HOPG and N-HOPG before and after CO2 adsorption. Figure 3b shows the O 1s XAS spectra of HOPG after CO2 adsorption for different incident angles θ.

adsorption is subtracted. The $\sigma^*$ (540 eV) and $\pi^*$ (532 eV) peaks are enhanced at surface normal (0°) and grazing (70°) incidence, respectively. The observed $\pi^*$ orbital would be derived from the 2b$_1$ orbital (perpendicular to the CO$_2$ plane) caused by the splitting of CO$_2$ LUMO orbitals. Therefore, this polarization dependence of O 1s XAS indicates that the CO$_2$ molecules are lying flat on the N-HOPG surface. Although the energy position of the 6a$_1$ orbital sharply decreases upon bending, the energy position of the 2b$_1$ orbital remains nearly constant relative to that of the 2$\pi$$_u$ orbital, as shown in Fig. 2d. The observed $\pi^*$ peak is ~2.8 eV lower than the $\pi^*$ peak (2$\pi$$_u$ orbital) for the gas-phase linear CO$_2$ at 534.8 eV [29], mainly because of the observed chemical shift of the O 1s core level in XPS, as discussed above.

The IRAS spectrum in Fig. 3b also supports the above CO$_2$ configuration; considering the selection rule of IRAS, the absence of peaks at approximately 1200–1300 cm$^{-1}$ and 1600 cm$^{-1}$, expected for the symmetric and asymmetric OCO-stretching modes of the bent CO$_2^-$ carboxylate with its molecular plane perpendicular to the surface [25], suggests the CO$_2$ to be lying flat on the surface. Both the O 1s XAS spectra and the IRAS spectrum of the N-HOPG support this configuration of the adsorbed CO$_2$.

Figure 3c shows the N 1s XAS spectra of the N-HOPG before CO$_2$ adsorption for different incident angles of 0°, 45°, and 70°. The spectra are normalized according to the intensity at 430 eV. Three sharp peaks in the $\pi^*$ region can be assigned to pyridinic N (A), cyanide N (B), and graphitic N (center N and valley N) (C) [12, 30]. A peak at 407.5 eV corresponds to the $\sigma^*$ state of the nitrogen components. The intensities of the pyridinic and graphitic N change with the X-ray incident angles, indicating that these components are incorporated into the planar graphite lattice via substitution [31]. The cyanide N, however, does not show any polarization dependence, suggesting multiple directions of the C≡N configuration. Since the adsorbed CO$_2$ also shows a highly oriented (lying flat) configuration, CO$_2$ adsorption sites should be introduced in the vicinity of the highly oriented pyridinic and graphitic N (center N and valley N).

Based on the Lewis acid/base-interaction picture, several research groups have reported possible mechanisms of CO$_2$ adsorption and reduction on nitrogen-doped carbon materials as follows: (1) hydrogen bonds forming between the carbon surface and oxygen atoms in a CO$_2$ molecule [6], (2) pyridonic N species as anchors for CO$_2$ capture [7], (3) a lone-pair electron located at a nitrogen atom [8], and (4) a localized electronic state of the graphite surface modified by doped nitrogen [20, 32–34]. The possibility of mechanism (1) can be excluded, because hydrogen atoms are much less prevalent in the large
platelet graphite used in this study can then be in graphene flakes. Mechanism (2) can also be excluded because pyridonic N species, located at approximately 400 eV [7], are not observed in the N 1s XPS spectrum. For the presence of a lone-pair electron that interacts with CO$_2$, the most probable amine functional groups, located at 399.4 eV [16], are not observed because of the pyrolysis at ~1000 K in this work, but pyridinic N, which is present in this work, provides a possibility for mechanism (3) [8]. We consider that mechanism (4) is the most probable for creating the active sites for CO$_2$ adsorption and reduction. The pyridinic N detected in our results may work as a Lewis base and interact with CO$_2$. Indeed, recent scanning tunneling spectroscopy measurements have revealed the presence of an electronic structure just 370 meV below the Fermi level of several localized carbon atoms surrounding pyridinic N at monovacancy sites [33]. The observed valley N site is also expected to modify the electronic structure of the surrounding carbon atoms and induce a local density of states of ~200–400 meV below the Fermi level [34], which may also provide CO$_2$ adsorption and reaction sites. Therefore, the interaction sites with CO$_2$ in N-HOPG would be provided by the lone-pair electrons of pyridinic N or the localized π states just below the Fermi level induced by the pyridinic N and/or valley N. According to the recent report with HOPG model catalysts, pyridinic N can create Lewis base sites for CO$_2$ adsorption on carbon materials [20], which is consistent with our present discussion. The clear evidence of the charge transfer from the substrate and the new information on the molecular orientations of both CO$_2$ and nitrogen moieties on the graphite substrate provide great insight into the CO$_2$ adsorption mechanism, and the Lewis basicity of nitrogen-doped graphite can be directly estimated by element-specific synchrotron analyses.

**Conclusions**

We have investigated the adsorbed CO$_2$ at 300 K on N-HOPG by XPS, angle-resolved XAS, and IRAS using a model N-HOPG synthesized by a protocol developed in a previous study. The O 1s binding energy of the adsorbed CO$_2$ at 300 K, located at 533 eV, showed clear evidence of the Lewis basicity of N-HOPG caused by the nitrogen dopant in the graphite system. The polarization dependence of the σ*- and π*-peaks in the O 1s XAS spectra, as well as the absence of expected IRAS signals, clearly indicates that the adsorbed CO$_2$ lies flat on the graphite surface and that Lewis base sites are induced by the incorporation of nitrogen in HOPG. We discussed possible CO$_2$ adsorption sites induced by pyridinic N and valley N species. The activity of these species as adsorption sites indicates the potential to fine-tune the Lewis basicity of a graphite substrate by controlling the prevalence of nitrogen species focused on the appropriate interaction strength of CO$_2$, which can be directly estimated by the O 1s binding energy of the adsorbed CO$_2$. The properties of fine-tuned Lewis basicity in carbon-based materials can be applied to the field of catalysis, including the use of the materials as oxygen reduction reaction or hydrogen evolution reaction sites.
