Abstract

Objective: A widely used chemical-mechanical method of gingival retraction can cause gingival tissue damage. The aim of this study was to test the influence of the chemical-mechanical gingival retraction procedures on the gingival bleeding index (GBI) and the salivary concentration of monocyte chemoattractant protein 1 (MCP-1) as an indicator of inflammatory changes in the gingiva. Materials and Methods: The effects of 2 different retraction agents (aluminum chloride and ferric sulfate) were compared, particularly their tissue damaging effect during tooth preparation. Therefore, GBI values and the salivary concentration of MCP-1 were assessed during the chemical-mechanical method of gingival retraction in a homogenous group of respondents. The subjects (\(n = 60\)) were divided into 2 experimental groups (G1 and G2) regarding the need for tooth preparing and making artificial crowns. Each group was further divided into 2 subgroups (R1 and R2) according to the type of the gingival retraction agent used (aluminum chloride and ferric sulfate). Results: Compared to the values at the study start, a statistically significant increase in GBI and salivary MCP-1 (\(p < 0.001\)) 1 day after gingival retraction agent application was observed in both experimental groups. After 72 h, the values were lower than in the second observation period but still statistically significantly higher compared to the study start (\(p < 0.001\)), which indicated the reversibility of the tissue changes. Conclusion: Higher values of the investigated parameters were observed in the group of subjects with prepared teeth, and clinical changes were more pronounced after the use of ferric sulfate.

Significance of the Study

- Two different retraction agents were compared with regard to the gingival bleeding index and levels of monocyte chemoattractant protein 1 (MCP-1).
- A statistically significant increase was observed in the gingival bleeding index 24 h after the application of the gingival retraction agent.
- A statistically significant increase in MCP-1 values was observed over the entire study period.

Gingival bleeding index · Retraction · Inflammation · MCP-1 · Monocyte chemoattractant protein · Astringent
**Introduction**

Fixed prosthodontic appliance therapy involves making artificial crowns or bridges for the purpose of rehabilitating the dental arch. A well-made fixed restoration intimately rests on the dental tissue in the region of the preparation boundary (demarcation line). Gingival retraction is necessary in cases in which the demarcation line is localized at or below the edge of the gingiva, with the aim of providing accurate imprinting [1].

The most commonly used chemical-mechanical method of gingival retraction involves the use of a retraction cord soaked in astringent fluid, most commonly aluminum and iron salts, to allow the marginal gingiva to reversibly dislocate apically and laterally and to permit the region of the gingival sulcus to drain. The mechanism of action of astringent is protein precipitation and inhibition of transcapillary movement of plasma proteins [2]. Astringent retraction agents reduce cellular permeability and drain gingival tissue, leading to its reversible recession. Protein precipitation and denaturation can cause local tissue damage [2–5]. The potential toxicity of aluminum chloride at concentrations > 10% has been demonstrated [6, 7]. Ferric sulfate coagulates blood, but often hemorrhage recurs after removal of the retraction cord, and the opening of the gingival sulcus is less than what is seen when aluminum salts are used [8]; the authors have reported possible tissue damage caused by ferric sulfate [8, 9].

The first signs of damage caused by the chemical-mechanical retraction procedure appear on the gingival tissue, and the resulting inflammation leads to an increase in the concentration of proinflammatory cytokines and immunoglobulins in saliva, as well as to structural changes in the tissue itself [10]. Gingival indices allow the numerical expression of the resulting changes and objective evaluation of the periodontal condition. Proinflammatory cytokines are associated with oral tissue destruction, proteinase induction, and bone decomposition, and their increased production has been observed in numerous oral diseases [11, 12]. Monocyte chemoattractant protein 1 (MCP-1) is a proinflammatory chemotactic cytokine that can trigger different groups of leukocytes through interaction with specific receptors and can induce the formation of specific inflammatory infiltrates; thus, it can be considered a sign of newly developed inflammation [13, 14]. Early detection of inflammation markers after standard dental procedures may help to prevent the occurrence of more severe periodontal damage.

The aim of this study was to test the influence of the chemical-mechanical gingival retraction procedure on gingival bleeding index values and the salivary MCP-1 concentration as an indicator of inflammatory changes in the gingiva.

**Materials and Methods**

**Subjects**

The study included 60 subjects of both sexes, nonsmokers, aged 20–40 years, with no systemic diseases and with a completely rehabilitated oral cavity. All subjects were examined and rehabilitated by the periodontist before the intervention, so that there were no inflammatory changes on the supporting dental tissues before examination onset. The subjects were divided into 2 experimental groups (G1 and G2) based on the need for tooth preparation and making artificial crowns. Each group was further divided into 2 subgroups (R1 and R2) [15] according to the type of the gingival retraction agent used (Table 1). Sample size was calculated using the commercial statistical program G*Power for two-way null hypothesis testing and the F test and ANOVA, respectively. The following parameters were specified: probability of type 1 error α = 0.05 and strength of the study of 0.8. With such initial parameters and based on the publication by DI Venere et al. [16], a minimum sample size of at least 8 subjects per subgroup of both study groups was obtained.

**Methods**

Determining the time and extent of bleeding, GBI numerically indicated the activity of the inflammatory process in the gingiva. Testing was performed by probing the gingival sulcus with a blunt-ended periodontal probe. The intensity of resulting bleeding was scored based on the behavior of the gingiva after probing: 0, no bleeding; 1, bleeding 10–30 s after probing; 2, bleeding during gingival probing; and 3, spontaneous bleeding of the gingiva. The examined index was determined by the same periodontologist before the retraction procedure as well as in other predicted retraction periods.

MCP-1 concentrations were determined using the human CCL2/MCP-1 Quantikine ELISA kit (sensitivity 10 pg/mL). Saliva samples were centrifuged at 10,000 rpm for 5 min. The separated supernatant was frozen at −80 °C until analysis.

Clinical Procedure
Subjects in the G1 group had been indicated for making an artificial crown, i.e., the preparation of 1 tooth, which precedes the retraction procedure. The preparation demarcation was located 0.25–0.5 mm below the gingival level, with maximum preservation of the gingival tissue integrity. Tooth preparation was performed atraumatically by the same type of dental bur and by 3 trained therapists, thus reducing the possibility of gingival inflammation due to mechanical damage to the gingiva. Since there was no tooth preparation in group G2, the chemical retraction method was demonstrated on the upper left central incisor.

The chemical-mechanical method of gingival retraction involved the application of a retraction cord (Elite Cord, Zhermack SpA, Italy) of the appropriate diameter, impregnated with R1 or R2, into the gingival sulcus of the reference tooth for 5 min. The retraction cord was atraumatically pressed by the same therapist along the entire scope of the tooth using a plastic instrument. The entire study period involved 3 observation periods: prior to (T0), and 24 h (T1) and 72 h (T2) after the chemical-mechanical retraction procedure. The first observation period (T0) in G1 was related to the time before tooth preparation. In each observation period, GBI was determined for the reference tooth, and a sample of nonstimulated saliva was collected into a sterile tube. Given that the test parameters in all subjects were determined prior to and after the retraction procedure, all samples collected before the treatment were considered as controls. Clinical procedures for making artificial crowns on prepared teeth followed the study period.

Statistical Analysis
The data were processed using the software for statistical data processing SPSS 15.0. The Mann-Whitney U test was used to assess significant differences (p) of continuous variables between 2 independent subject groups. A value of p < 0.05 was considered statistically significant. Changes in the arithmetic mean of the variables measured in the 3 observation periods in the study groups were analyzed using ANOVA for repeated measures (RM ANOVA). The effects of changes were defined by the values of the partial eta squared (ηp²) with the effect defined as “small” for parameter values > 0.01, “medium,” for values > 0.06, and “large” for values > 0.14.

Results
Table 2 shows a statistically significant increase in GBI values (p < 0.001) 24 h after the application of the gingival retraction agent in both experimental groups compared to the values at the beginning of the study. After 72 h, the values were lower compared to the second observation period, but they were still statistically significantly higher compared to those at the study onset (p < 0.001).

The influence of the type of the gingival retraction agent on GBI in the experimental groups during the entire study period is shown in Table 3. Within both groups, G1 and G2,
a statistically significant increase in GBI values was found for both tested retraction agents and for all subjects during the entire study period ($p < 0.001$). The gingival retraction agents showed major effects on the GBI value. In both groups, the effect size was greater with the use of the aluminum chloride-based gingival retraction agent (R1). Testing the effects between subgroups (between participant effects) showed that they did not differ statistically significantly in GBI values over the entire follow-up period.

Changes in GBI values during the study period were similar in both groups of subjects (Fig. 1). One day after the retraction procedure, both experimental groups experienced a statistically significant increase in the salivary concentration of MCP-1 ($p < 0.001$). After 72 h, the salivary concentration of MCP-1 was decreased compared to the second observation period, yet it remained statistically significantly higher than prior to the application of the gingival retraction agent ($p < 0.001$) (Table 4).

The effect of the gingival retraction agent type on the salivary concentration of MCP-1 during the study period in groups G1 and G2 is shown in Table 5. Within these groups, a statistically significant increase in MCP-1 values was observed over the entire study period ($p < 0.001$) for both retraction agent types and for all subjects, with a great effect of the retraction agent. Testing the effect of the retraction agent types between subgroups showed that they did not differ statistically significantly in MCP-1 concentrations throughout the study period, with a negligible effect of the gingival retraction agent used.

Changes in MCP-1 concentrations during the study period occurred in a statistically significantly different manner depending on the retraction agent type only in the group of subjects with nonprepared teeth ($p < 0.001$), with a great effect of the retraction agent. In group G1, changes in MCP-1 concentrations did not occur in a statistically significantly different manner in the subgroups (Fig. 2).

**Discussion**

The study started from the assumption that the widely used chemical-mechanical procedure of gingival retraction during the production of fixed prosthetic compensations may damage the treated gingival tissue and may
cause an acute inflammatory reaction, as evidenced by the increase in the GBI value, which serves as a clinical parameter, as well as the salivary concentration of MCP-1, a marker of inflammation.

The results of the study indicate reversible damage to the gingival tissue after the application of both retraction agents studied. The clinical observation of the gingival tissue in the subjects revealed a mild-to-moderate inflammation 1 day after the retraction procedure, which resulted in bleeding during gingival sulcus probing in all subjects in the prepared teeth group as well as after the application of ferric sulfate in subjects with nonprepared teeth. Three days after the gingival retraction, inflammation was reduced, and bleeding after probing was mild in group G1, while in group G2 it was less. These results are in agreement with the results of other authors, who demonstrated the recovery of oral tissue after retraction procedures [17, 18]. Higher GBI values in subjects with prepared teeth indicated a certain mechanical tissue injury that contributed to the inflammatory response of the gingiva [19].

Proinflammatory cytokines play important roles in triggering and maintaining inflammatory and immune responses [10]. The chemical-mechanical retraction method led to an increase in the MCP-1 concentration in the subjects of both experimental groups, which is in a positive correlation with the results of the clinical parameter monitored. A decrease in MCP-1 with time proved the reversibility of the resulting changes. The type of the retraction agent used did not affect the measured MCP-1 concentration, but its mean values were higher in group G1, which emphasizes the importance of tooth preparation in the inflammatory reaction observed in the gingival tissue.

Our results are consistent with the results of other studies published to date and indicate that increased MCP-1 secretion is an indicator of periodontal damage [20–22]. Garlet et al. [21] demonstrated that MCP-1 in diseased gin-

Fig. 2. MCP-1 concentrations (pg/mL) during the study period in groups G1 (a) and G2 (b) with regard to the gingival retraction agent used.
Gingival tissue supports the maturation of monocytes into macrophages, whose role is to destroy pathogens and secrete proinflammatory mediators. Macrophage-released products such as IL-1 and TNFα, in addition to contributing to the inflammatory reaction, also trigger bone decomposition [22]. Therefore, the chemotactic action MCP-1 on monocytes and macrophages can support chronic inflammatory responses and bone loss present in periodontopathy [12]. In the gingival fluid of patients with aggressive and chronic periodontitis, MCP-1 levels were higher than in healthy subjects [23, 24]. In a study by Pradeep et al. [12], a proportionate decrease in MCP-1 levels was noted in the gingival fluid after periodontal therapy.

To date, the results of the potential iatrogenic effect of the chemical-mechanical retraction procedure have been obtained in in vitro and in vivo studies in experimental models, whereas studies in clinical conditions are insufficient and, at the same time, necessary from the professional point of view. The study of clinical parameters of gingival damage and the determination of the salivary concentration of the reference proinflammatory cytokine in a homogeneous group of patients have given an exact answer regarding potential side effects of the widely used chemical-mechanical method of gingival retraction. The right choice of clinical procedures and therapeutic agents diminishes iatrogenic damage that would compromise the effect of prosthetic therapy and reduce the durability of fixed restoration.

Conclusion

The bleeding index values and the salivary concentration of MCP-1 increased statistically significantly after the chemical-mechanical gingival retraction procedure, with a tendency to decrease over time, which indicated the reversibility of the resulting changes. Higher values of the studied parameters were observed in the group of subjects with prepared teeth, and clinical changes were more pronounced after the use of ferric sulfate, although no statistically significant difference was found.
