ABSTRACT

Merging galaxy clusters have become one of the most important probes of dark matter, providing evidence for dark matter over modified gravity and even constraints on the dark matter self-interaction cross-section. To properly constrain the dark matter cross-section it is necessary to understand the dynamics of the merger, as the inferred cross-section is a function of both the velocity of the collision and the observed time since collision. While the best understanding of merging system dynamics comes from $N$-body simulations, these are computationally intensive and often explore only a limited volume of the merger phase space allowed by observed parameter uncertainty. Simple analytic models exist but the assumptions of these methods invalidate their results near the collision time, plus error propagation of the highly correlated merger parameters is unfeasible. To address these weaknesses I develop a Monte Carlo method to discern the properties of dissociative mergers and propagate the uncertainty of the measured cluster parameters in an accurate and Bayesian manner. I introduce this method, verify it against an existing hydrodynamic $N$-body simulation, and apply it to two known dissociative mergers: 1ES 0657-558 (Bullet Cluster) and DLSCL J0916.2+2951 (Musket Ball Cluster). I find that this method surpasses existing analytic models—providing accurate (10% level) dynamic parameter and uncertainty estimates throughout the merger history. This, coupled with minimal required a priori information (subcluster mass, redshift, and projected separation) and relatively fast computation ($\sim 6$ CPU hours), makes this method ideal for large samples of dissociative merging clusters.

Key words: galaxies: clusters: individual (1ES 0657-558, DLSCL J0916.2+2951) – gravitation – methods: analytical – methods: statistical

1. INTRODUCTION

Merging galaxy clusters have become important astrophysical probes providing constraints on the dark matter (DM) self-interaction cross-section ($\sigma_{\text{DM}}$; Markevitch et al. 2004; Randall et al. 2008; Merten et al. 2011; Dawson et al. 2012) and the large-scale matter-antimatter ratio (Steigman 2008). They are a suspected source of extremely energetic cosmic rays (van Weeren et al. 2010), and the merger event potentially affects the evolution of the cluster galaxies (e.g., Poggianti et al. 2004; Hwang & Lee 2009; Chung et al. 2009). All of the respective astrophysical conclusions drawn from merging clusters depend on the specific dynamic properties of a given merger.

For example, the subclass of dissociative mergers, in which the collisional cluster gas has become dissociated from the near collisionless galaxies and dark matter, provides four ways of constraining the dark matter self-interaction cross-section (Markevitch et al. 2004; Randall et al. 2008). The best constraints come from studying the mass-to-light ratios ($M/L$) of the subclusters and the offset between the collisionless galaxies and dark matter (Markevitch et al. 2004; Randall et al. 2008). Both constraints directly depend on the merger dynamics. First the relative collision velocity will affect the expected momentum transfer between each subcluster’s dark matter particles, which will in turn affect the expected dark matter mass transfer from the smaller subcluster to the larger subcluster, ultimately affecting the expected mass-to-light ratios of the clusters (Markevitch et al. 2004). Second the expected galaxy–dark matter offset will depend on the observed time since collision (TSC). Initially the offset between the galaxies and dark matter will increase with TSC (for $\sigma_{\text{DM}} > 0$) as the collisionless galaxies outrun the dark matter that experienced a drag force during the collision, and then at later TSC the offset will decrease due to the gravitational attraction between the galaxies and dark matter halo. Additionally it is important to know the velocity so that dark matter candidates with velocity-dependent cross-sections (e.g., Colín et al. 2002; Vogelsberger et al. 2012) can be constrained.

However, there is no way to directly observe the dynamic merger parameters of principal interest: the three-dimensional relative velocity ($v_{3D}$) and separation ($d_{3D}$) of the subclusters as a function of time, their maximum separation ($d_{\text{max}}$), the period of collisions ($T$), and the TSC. Observations are generally limited to: the subcluster projected separation ($d_{\text{proj}}$), the line-of-sight (LOS) velocity of each subcluster ($v_{l}$) as inferred from their redshifts, and their mass ($M_i$) or projected surface mass density profile. In addition to the obvious inability to measure a change in the merger state, it is difficult to constrain the dynamic parameters of interest even in the observed state. This is due to the general inability to constrain the angle of the merger axis with respect to the plane of the sky ($\alpha$); see Figure 1.

For the Bullet Cluster it was originally thought that estimates of the Mach number of the cluster merger through X-ray observations of the gas shock feature (e.g., Markevitch 2006) could be used to estimate $v_{3D}$ and, in conjunction with measurements of the relative LOS velocities, then estimate $\alpha$. Similarly, the gas pressure differential across cold front features seen in

---

1 I define subcluster as either one of the two colliding clusters, irrespective of mass, and I define cluster as the whole two-subcluster system.

2 I define the time of collision to be the time of the first pericentric passage.
some merging clusters has also been used to estimate the Mach number of the cluster merger (e.g., Vikhlinin & Markevitch 2003). However, Springel & Farrar (2007) showed that the Mach number only translates to an upper limit on $v_{3D}$. There is potential for constraining $\alpha$ using polarization measurements of radio relics (Ensslin et al. 1998), which are associated with some cluster mergers (e.g., van Weeren et al. 2010) but not all (e.g., Russell et al. 2011). Even if for some mergers radio relics provide constraints on $\alpha$, dynamic models are still needed in order to ascertain the dynamic properties of the merger throughout time.

The two most prevalent methods for ascertaining the dynamics of observed merging systems are the timing argument and $N$-body simulations. The timing argument is based on the solution to the equations of motion of two gravitating point masses, with the cosmological constraint that as $z \rightarrow \infty$ the separation of the two masses $d_{3D} \rightarrow 0$ (for an exposition of this method see Peebles 1993). The timing argument was first used by Kahn & Woltjer (1959) to study the system of the Milky Way and M31, and first applied to binary cluster systems by Beers et al. (1982). It has recently been applied to several dissociative mergers, including the Bullet Cluster (Barrena et al. 2002), A520 (Girardi et al. 2008), A2163 (Bourdin et al. 2011), and A1758N (Boschin et al. 2012). $N$-body simulations of observed dissociative mergers have been limited to the Bullet Cluster (1ES 0657-558) and have come in two variants: hydrodynamic (Springel & Farrar 2007; Milosavljević et al. 2007; Mastropietro & Burkert 2008) and self-interacting dark matter (SIDM) plus collisionless galaxy particles (Randall et al. 2008).

While the timing argument method is easy to use, its inherent assumptions result in non-negligible error for dissociative systems. Most importantly the timing argument method assumes two point mass particles; this assumption begins to break down as the two subclusters overlap and results in divergent solutions as the subclusters near collision. Since most dissociative mergers are observed with the two-subcluster halos overlapping and dark matter constraints depend on the merger dynamics near collision, application of the traditional timing argument to dissociative mergers is limited and should be done with caution. Nusser (2008) addressed this weakness of the traditional timing argument by substituting truncated Navarro et al. (1996, hereafter NFW) halos and numerically solving the equations of motion. Another weakness of the timing argument is that its main constraint requires the assumption that the subcluster masses are constant since the beginning of the universe. While Angus & McGaugh (2008) have noted this problem with the initial conditions of $N$-body simulations and proposed a solution...
Figure 3. The posterior of the Bullet Cluster’s TSC0 and $v_{3D}$ parameters is shown in grayscale with dark and light blue contours representing 68% and 95% confidence, respectively. The green-scale triangles are from a subsample of the Monte Carlo population, which jointly satisfies the requirement of being drawn from $\pm 0.01 \sigma$ of the mean of each of the input parameters, i.e., the “most likely” values for the input parameters. Despite representing the most probable input parameter values, there is considerable spread in the inferred output parameters, with the subsample clearly tracing the ridge of the distribution. The saturation of the triangles increases with increasing $\alpha$, from 10 to 86 deg. The purple-scale circles are from a subsample near the bi-weight location of $\alpha = 50 \pm 0.0002$ deg, with the saturation of the circles increasing with increasing $M_{200}$. While the length of the distribution is predominantly caused by uncertainty in $\alpha$, the width is predominantly caused by uncertainty in the input parameters. Despite the Bullet Cluster being one of the best measured dissociative mergers, there is still considerable and complex uncertainty in its merger parameters, predominantly due to uncertainty in $\alpha$.

(A color version of this figure is available in the online journal.)

Figure 4. The posterior of the Bullet Cluster’s TSC0 and $v_{3D}$ parameters after application of an additional temporal prior based on X-ray observations of the Bullet Cluster (grayscale). Dark and light blue contours represent 68% and 95% confidence, respectively. The added temporal prior significantly improves the constraint on the merger parameters (compare with Figure 3). The black diamond represents the Springel & Farrar (2007) hydrodynamic simulation result for their defined “observed state,” whose X-ray properties best match the observed X-ray properties; $d_{3D} = 625$ kpc for this state. The green bar shows their result for $d_{3D}$ between 700 and 900 kpc, which is more in line with the observed $d_{3D} = 720 \pm 25$ kpc (assuming 0 deg $< \alpha < 35$ deg).

(A color version of this figure is available in the online journal.)

et al. (2012) have come the closest to addressing this issue in their investigation of potential dissociative mergers (A665 and AS1063) through the use of simplified scale-free numerical simulations of the mergers (see Gómez et al. 2000, for details). However, they have still had to severely limit the phase space probed (fixing merger parameters such as the initial relative velocity and subcluster-subcluster mass ratio); thus, admittedly this approach enables construction of plausible models, but not a thorough accounting of possible or likely models.

With these weaknesses in mind I present a new method\footnote{This method is similar to the one used by Dawson et al. (2012), although with several improvements (see Section 4).} for analyzing the dynamics of observed dissociative mergers. My primary objectives are to (1) obtain a solution valid near the collision state, (2) fully estimate the covariance matrix for the merger parameters, (3) be able to analyze a dissociative merger on the order of a day using a typical desktop computer, and (4) obtain approximately 10% accuracy; all assuming that only the most general merger observables and their uncertainty are known: mass of each subcluster, redshift of each subcluster, and projected separation of the subclusters.

In Section 2 I define a method for analyzing the dynamics of observed dissociative mergers. In Section 2.3 I verify this method with existing results from a hydrodynamic $N$-body simulation. In Section 3 I apply this method to the Bullet Cluster, and in Section 4 I apply this method to the Musket Ball Cluster (DLSCQ J0816.2+2951) and contrast its dynamics with those of the Bullet Cluster. Finally in Section 5 I summarize my findings, discuss their implications for the constraints on dark matter, and suggest other science that will benefit from the introduced method. Throughout this paper I assume $\Omega_{\Lambda} = 0.7$, $\Omega_{m} = 0.3$, and $H = 70$ km s$^{-1}$ Mpc$^{-1}$.

3 (1) Bullet Cluster (Clowe et al. 2004); (2) A520 (Mahdavi et al. 2007); (3) MACS J0025.4-1222 (Bradač et al. 2008); (4) A1240 (Barrena et al. 2009); (5) ZwCl 0008.8+5215 (van Weeren et al. 2011); (6) A2744 (Merten et al. 2011); (7) A2163 (Okabe et al. 2011); (8) A1755 (Ragozzine et al. 2012); (9) Musket Ball Cluster (Dawson et al. 2012); (10) ACT-CL J01024915 (Menanteau et al. 2012); (11) MACS J0717.5+3745 (Mroczkowski et al. 2012).

4 Based on estimating the mass accretion histories of the clusters (e.g., Wechsler et al. 2002), their correction is incompatible with the timing argument method as this would add a second differential term to the equations of motion. Finally, the large covariance between the merger parameters plus the complexity of the equations of motion make propagation of errors in the timing argument formalism untenable. This has resulted in a lack of certainty with timing argument results, leaving most users to run a few scenarios in an effort to roughly bound the range of possible solutions (e.g., Boschin et al. 2012).

$N$-body simulations provide the most accurate description of merger dynamics; however, they are computationally expensive, which results in their application being limited. Despite 11 currently confirmed dissociative mergers, only the Bullet Cluster has been modeled with $N$-body simulations, whereas most of these have been analyzed with the timing argument method. Existing $N$-body simulation strategies to ascertain the dynamic properties of mergers are incapable of keeping up with the current faster than exponential rate of discovery. Even for the case of the Bullet Cluster the $N$-body analyses have been limited as far as mapping out the merger dynamic phase space allowed by the uncertainty of the observations, with at most 15 different scenarios being run (Mastropietro & Burkert 2008). Gómez\footnote{This method is similar to the one used by Dawson et al. (2012), although with several improvements (see Section 4).}
2. METHOD

In order to obtain a valid solution of the system dynamics near the collision state I use a model of two spherically symmetric NFW halos, rather than point masses. I incorporate this model in a standard Monte Carlo implementation: draw randomly from the observables’ probability density functions (PDFs) to generate a possible realization of the merger, use the model to calculate merger properties of interest, apply multiple priors, store these likelihood weighted results as a representative random draw of their PDF, and repeat. The final result is a multidimensional PDF for the dynamic parameters of the merger. This method agrees well with hydrodynamic simulations (Section 2.3) and satisfies the speed and accuracy objectives outlined in the Introduction.

2.1. Model

The general basis of the model is a collisionless two-body system with the mass of each body mutually conserved throughout the merger. The model requires minimal input: the mass of each subcluster, the redshift of each subcluster, and the projected separation of the subclusters (along with associated uncertainties). It assumes conservation of energy and zero angular momentum. The model also assumes that the maximum relative velocity of the two bodies is the free-fall velocity of the system assuming their observed mass. In the remainder of this subsection I will discuss in detail these general assumptions, their justification, and their implications.

I model the system using two spherically symmetric NFW halos truncated at $r_{200}$. By default the concentration of each halo is determined by the halo’s mass via the mass–concentration scaling relation of Duffy et al. (2008). This is not a requirement of the model though, and measured concentrations can be used, as in the case of Section 3.1. The dynamic parameter results are relatively insensitive to the assumed concentration of the subclusters. Take for example the case of Section 2.3 with user specified concentrations of $c_1 = 1.94$ and $c_2 = 7.12$: if instead Duffy et al. (2008) inferred concentrations $c_1 = 3.44$ and $c_2 = 2.75$ ($\sim 200\%$ difference for both) are used, the differences in the estimated $v_{3D}(t_{col})$ and TSC are both less than 6%.

The model assumes that the mass of each subcluster is constant and equal to the observed mass. While this assumption is also used in the timing argument method, it is more reasonable for this method since the bulk of the results are calculated between the observed state and the collision state, typically lasting $\lesssim 1$ Gyr. This is about an order of magnitude shorter than the typical timescales of the timing argument method; thus, the new method is less susceptible to error due to neglecting growth of structure.

The model assumes that the energy of the two-halo system is conserved, and consists only of their mutual kinetic and potential energies. The kinetic energy of the system is $K(t) = 0.5 \mu v_{3D}(t)^2$, where $\mu$ is the reduced mass of the system and $v_{3D}(t)$ is the relative physical velocity of the two subclusters at time $t$. The potential energy of the system is assumed to be purely gravitational and is derived in Appendix A. Since the model assumes zero impact parameter, there is no rotational kinetic energy term. Mastropietro & Burkert (2008) find that a moderate impact parameter of $\sim 0.1 r_{200}$ has less than a 1% effect on the merger velocity; thus, this assumption should have

---

5 $r_{200}$ is defined as the radius of the spherical region within which the average density is 200 times the critical density at the respective redshift.

6 For subcluster mass I refer to $M_{200}$, which is the mass of the individual subcluster enclosed within a radius of $r_{200}$.
 negligible effect for the case of dissociative mergers which must have had relatively small impact parameters in order to dissociate the bulk of their gas.

For the relative velocity of the two subclusters I apply a flat prior from zero to the free-fall velocity of the subclusters, assuming their observed mass. This will result in an overestimate of the maximum possible relative velocity, due to the neglect of mass accretion. It is conceivable that this prior could be tightened using the maximum relative velocities observed in cosmological N-body simulations as a function of subcluster masses and redshift. Another possibility for tightening the prior would be to analytically estimate the free-fall velocity accounting for mass accretion (e.g., Angus & McGaugh 2008). An advantage of the Monte Carlo approach taken with this method is that additional priors can be applied as more knowledge becomes available without the need to rerun the analysis, so I opt for a conservative default approach.

The model ignores the effects of surrounding large-scale structure and simply treats the two-body system. As Nusser (2008) shows, a global overdense region (10 times denser than the background) engulfing the system only affects the dynamics substantially for extreme collision velocities (~4500 km s^{-1}). While global overdensities may be disregarded, it is not clear that the effects of nearby structures can be disregarded, e.g., as in the case of three-body systems. Thus, this method should be applied with caution to complex cluster mergers.

The model also ignores dynamical friction. Farrar & Rosen (2007) found that including dynamical friction accounted for an ~10% reduction in the inferred collision velocity of the Bullet Cluster in their analytic treatment. This is potentially concerning since dynamical friction is inversely proportional to the relative velocity of the merger; thus, it may become even more important for mergers slower than the Bullet Cluster. However, in Section 2.3 I compare the results of my method with those from a hydrodynamic N-body simulation and show that the net effect of all simplifications (including ignoring dynamical friction and tidal stripping of mass and gas mass lost during the collision) is negligible, suggesting that dynamic friction is less important than the analytic estimates of Farrar & Rosen (2007) suggest.

2.2. Monte Carlo Analysis

In this section I discuss the details of the Monte Carlo analysis workflow. I chose to implement a Monte Carlo analysis because the high degree of correlation among the many merger dynamic parameters made traditional propagation of errors unfeasible. A Monte Carlo analysis has the added advantage of easily enabling application of different combinations of priors ex post facto (see, e.g., Section 3.2.2).

The analysis begins by randomly drawing from the PDFs of the merger observables: mass of each subcluster ($M_{200}$), redshift of each subcluster ($z_i$), and projected separation of the subclusters ($d_{proj}$). The potential energy, $V$ (see Appendix A), at the time of the collision is used to calculate the maximum relative velocity,

$$v_{3D_{max}} = \sqrt{-\frac{2}{\mu} V(r = 0)}.$$

The velocity of each subcluster relative to us is estimated from its redshift,

$$v_i = \left[\frac{(1 + z_i)^2 - 1}{(1 + z_i)^2 + 1}\right] c,$$

where $c$ is the speed of light. The relative radial velocity of the subclusters is calculated from their redshifts,

$$v_{\text{rad}}(t_{\text{obs}}) = \frac{|v_2 - v_1|}{1 - \frac{v_{12}}{c^2}}.$$

Since the angle of the merger axis with respect to the plane of the sky, $\alpha$, is unconstrained without prior knowledge of the three-dimensional relative velocity, I assume that all merger directions are equally probable. However, projection effects result in PDF($\alpha$) = cos($\alpha$). Due to symmetry it is only necessary to analyze the range $0 \deg \leq \alpha \leq 90 \deg$. I draw randomly from
this PDF for each realization. This enables the calculation of the three-dimensional relative velocity in the observed state,

\[ v_{3D}(t_{\text{obs}}) = v_{\text{rad}}(t_{\text{obs}}) / \sin(\alpha), \]  

(1)

as well as the observed three-dimensional separation of the subclusters,

\[ d_{3D}(t_{\text{obs}}) = d_{\text{proj}} / \cos(\alpha). \]  

(2)

If \( v_{3D}(t_{\text{obs}}) > v_{3D_{\text{max}}}, \) then this realization of the merger is discarded; otherwise the relative collision velocity is calculated,

\[ v_{3D}(t_{\text{col}}) = \sqrt{\frac{2}{\mu} [V(t_{\text{obs}}) - V(t_{\text{col}})]}, \]  

(3)

Similarly if \( v_{3D}(t_{\text{col}}) > v_{3D_{\text{max}}}, \) then this realization is discarded.

The change in time, \( \Delta t \), between two separations is given by

\[ \Delta T = \int_{r_1}^{r_2} \frac{dr}{\sqrt{\frac{2}{\mu} (E - V(r))}}. \]  

(4)

I define the TSC as the time it takes the subclusters to traverse from zero separation to their physical separation in the observed state, \( d_{3D} \). Because there is a potential degeneracy in whether the subclusters are “outgoing” (approaching the apoapsis after collision) or “incoming” (on a return trajectory after colliding and reaching the apoapsis); I solve for both of these cases, \( TSC_0 \) and \( TSC_1 \), respectively. In determining \( TSC_1 \) it is useful to define the period, \( T \), of the system. I define \( T \) to be the time between collisions,

\[ T = 2 \int_0^{d_{\text{max}}} dr / \sqrt{\frac{2}{\mu} (E - V(r))}, \]

where \( d_{\text{max}} \) is the distance from zero separation to the apoapsis, when \( E = V \). Thus,

\[ TSC_1 = T - TSC_0. \]

During the Monte Carlo analysis any realizations with \( TSC_0 \) greater than the age of the universe at the cluster redshift are discarded. A similar flat prior is applied when calculating the statistics of \( TSC_1 \). To this regard some insight into the likelihood of the system being in an “outgoing” or “incoming” state can be gained by calculating the fraction of realizations with \( TSC_1 \) less than the age of the universe at the cluster redshift. Conceivably these temporal priors could be strengthened, requiring that the time to first collision \( (T) \) plus the respective TSC be less than the age of the universe at the cluster redshift, in a fashion similar to the timing argument. However, as with the timing argument model, the model of Section 2.1 becomes less valid over time-scales approaching the age of the universe. Thus, I use the more conservative prior by default.

Since the majority of the merger time is spent at large separations, due to lower relative velocities, observations of the system are more likely near apoapsis than near the collision. Thus, the probability of each realization is convolved with the prior

\[ \text{PDF}(TSC_0) = \frac{2TSC_0}{T}. \]  

(5)

However, this information is rarely if ever known, and thus it is not included by default. In Section 3.2.2 I show how additional temporal priors, based on similar effects, may be effectively applied to the results of the analysis ex post facto.

The end result of this method is a 13-dimensional posterior PDF of an array of cluster merger parameters (see, e.g., Appendix C). Finally to compact the results I use the biweight-statistic (generally more robust and less sensitive to abnormally tailed distributions than the median or mean) and bias-corrected percent confidence limits (Beers et al. 1990) applied to the marginalized parameter distributions of the valid realizations (see, e.g., Table 2).

### 2.3. Comparison with Hydrodynamic Simulations

For the purposes of checking the physical assumptions of the model I reanalyze the Springel & Farrar (2007) model of the Bullet Cluster, comparing my dynamic parameter estimates with their hydrodynamic N-body simulation based estimates. For this analysis I run just their single case through the model (i.e., I do not perform a Monte Carlo analysis). They represent the “main” and “bullet” subclusters as NFW halos with \( M_{200,\odot} = 1.5 \times 10^{15} \ M_{\odot}, c_1 = 1.94 \) and \( M_{200,\odot} = 1.5 \times 10^{14} \ M_{\odot}, \) and \( c_2 = 7.12, \) respectively. They note that the gas properties of their simulation most closely match the observed Bullet Cluster gas properties for the time step corresponding to a subcluster separation of \( d_{3D} = 625 \) kpc and relative velocity of \( v_{3D}(t_{\text{obs}}) = 2630 \) km s\(^{-1}\). I define this as the “observed” state (dashed line in Figure 2) and use the model discussed in Section 2.1 to extrapolate values of the relative subcluster velocities \( v_{3D} \) and time-since-observed state (TSO) before and after the observed state (left and right of the dashed line in Figure 2, respectively). The Springel & Farrar (2007) simulation results (black circles) for these parameters are read directly from their Figure 4.

I compare the model results (blue boxes) with the Springel & Farrar (2007) simulation results, and assume their results as truth when calculating the percent error; see Figure 2. There is better than 14% agreement between \( v_{3D} \) and 14% agreement between the TSO. While the model results are biased, the bias appears stable and is roughly an order of magnitude smaller than the typical random error in the parameter estimates (see, e.g., Table 2). Given the stability of the bias it is conceivable that it could be corrected in the model results. However, to have any confidence in this bias correction the model results should be compared with a range of merger scenarios, which is beyond the scope of this current work. Note that the better agreement between the velocity estimates than between the TSO estimates is to be expected since the velocity calculation (essentially Equation (3)) comes from simply comparing the observed and another state of the merger whereas the TSO calculation (Equation (4)) requires integration between these two states. The results of this comparative study essentially validate many of the simplifying assumptions of the model (conservation of energy, and ignoring the affects of dynamical friction and tidal stripping of dark matter and gas during the collision).

As an aside it should be noted that for this comparison I use the Springel & Farrar (2007) NFW halo parameters that represent the state of the halos prior to collision. Ideally I should use the NFW parameters representative of the state of the halos at \( t_{\text{obs}} \); however, these properties were not reported in their paper. From Figure 5 of Springel & Farrar (2007) some insight into the time variability of the halo parameters can be gained. Since the depth
of each halo’s gravitational potential at \( \sim r_{200} \) does not change appreciably throughout the merger, it can be inferred that \( M_{200} \) of each halo does not change. However, the gravitational potential near the center of each halo deepens by \( \sim 25\% \) during and after the collision. This can be interpreted as the concentration of each halo increasing. Thus, for the comparison of my model with the Springel & Farrar (2007) hydrodynamic simulation to be more appropriate I should have used halos with larger concentrations. Doing so actually brings my model results more in line with the simulation results. If for example I increase the concentration of the “bullet” halo from 1.94 to 3 and the concentration of the “main” halo from 7.12 to 8, then the percent error for the relative velocity of the halos reduces to \( \lesssim 1\% \) and the percent error for the TSO reduces to \( \sim 10\% \). Thus, the comparative results of Figure 2 should be considered conservative with respect to the variability of the halo properties throughout the merger.

3. BULLET CLUSTER DYNAMICS

The Bullet Cluster is the prime candidate for first application of the method as it is one of the best-studied dissipative mergers. It has a wealth of observational data necessary for input to the model, as discussed in Section 3.1, plus supplementary data which enable additional posterior priors, as discussed in Section 3.2.2.

3.1. Bullet Cluster Observed System Properties

I summarize the observed Bullet Cluster parameters used as input to my analysis in Table 1. The full PDFs of these input parameters have not been published so I simply assume Gaussian distributions. I refer to the main subcluster as halo 1 and the “bullet” subcluster as halo 2. For the mass and concentration of each subcluster I use the most recently reported estimates from Springel & Farrar (2007), based upon strong and weak lensing estimates (Bradaˇc et al. 2006). However, they do not present errors for these quantities so for the mass I estimate the \( 1\sigma \) errors to be 10\% of the mass, since this is approximately the magnitude of the error reported by Bradaˇc et al. (2006) for \( M \) (\(< 250\) kpc). There is no published estimate for the uncertainty of the concentrations of the NFW model fits, \( c_i \), so I simply assume the concentrations to be known quantities (as noted in Section 2.1 the results are relatively insensitive to the assumed concentrations). The redshifts of the main and “bullet” subclusters are estimated from 71 and 7 spectroscopic members, respectively (Barrena et al. 2002). The projected separation of the mass peaks is determined from strong and weak lensing measurements (Bradaˇc et al. 2006), and is essentially the same as the separation of the subclusters’ galaxy centroids. For each Monte Carlo realization individual values are drawn randomly from each of these assumed Gaussian distributions.

3.2. Bullet Cluster System Dynamics Results

I first analyze the Bullet Cluster with the Monte Carlo analysis method and default priors discussed in Section 2, highlighting the complexity of merger dynamics and the inappropriateness of analyzing a small sample of select merger scenarios. In Section 3.2.2 I incorporate additional constraints provided by the observed strong X-ray shock front plus boosted temperature and luminosity. I discuss this prior information and apply it ex post facto to the default prior results of Section 3.2.1.

I perform the analysis with 2,000,000 Monte Carlo realizations. Parameter estimates converge to better than a fraction of a percent with only 20,000 realizations (\( \sim 6 \) CPU hours). I run a factor of a hundred more since it was computationally inexpensive and it provides a data sample to which I can apply any number of conceivable posterior PDFs and still maintain sub-percent statistical accuracy.

3.2.1. Default Priors

The main results of this analysis are that (1) there is a great degree of covariance between the geometry, velocity, and time parameters of the merger, and (2) models of the system which disregard the uncertainty of \( \alpha \) will catastrophically fail to capture the true uncertainty in the dynamic parameters.

The two-dimensional PDF of Figure 3 exemplifies the complexity of the covariance between the various merger parameters.\(^7\) The shape of the PDF is most easily understood in terms of the parameters’ dependence on \( \alpha \). This dependence is illustrated by the green-scale triangles that represent a subsample of the Monte Carlo population, which jointly satisfies the requirement of being drawn from \( \pm 0.13\sigma \) of the mean of each of the input parameters, i.e., the “most likely” values for the input parameters. The saturation of the triangles increases with increasing \( \alpha \), from 10 to 86 deg, clearly showing a monotonically increasing relationship with TSC\(_0\) (see also Appendix C). For small \( \alpha \) (light green triangles), Equation (1) states that \( v_{3D}(t_{\text{obs}}) \) must be large and thus \( v_{3D}(t_{\text{col}}) \) must also be large, and since Equation (2) states that \( d_{3D}(t_{\text{obs}}) \) approaches the minimum possible observed separation, \( d_{\text{proj}} \), the TSC\(_0\) must approach a minimum. Conversely for large \( \alpha \) (dark green triangles), \( d_{3D}(t_{\text{obs}}) \) becomes large, increasing the time required to reach the observed state, and despite \( v_{3D}(t_{\text{obs}}) \) approaching the minimum \( v_{1D}(t_{\text{obs}}) \), the collision velocity must increase for the subclusters to have been able to reach the larger \( d_{3D}(t_{\text{obs}}) \).

The bulk of the uncertainty in the geometry, velocity, and time parameters is due to the uncertainty of \( \alpha \). This is exemplified by the fact that the green-scale triangles in Figure 3 closely trace the extent of the ridge line of the two-dimensional distribution (i.e., span the bulk of the uncertainty). Conversely the “width” of the distribution is predominantly due to uncertainty in the input parameters. This is exemplified by the purple circles of Figure 3, which are for a near constant \( \alpha \) yet randomly sample

\(^7\) Similar degrees of complex covariance exist for the other geometry, velocity, and time parameters, see, e.g., the results array in Appendix C.
the $M_{200}$ distribution. The saturation of the circles increases with increasing mass.

The inability to directly measure $\alpha$, coupled with its strong degree of correlation with the other dynamic parameters, makes it the dominant source of uncertainty. While it was originally believed that the three-dimensional merger velocity as inferred from the X-ray shock feature could be coupled with the redshift determined radial velocity to measure $\alpha$, Springel & Farrar (2007) showed that the X-ray shock inferred velocity significantly overestimates the true three-dimensional merger velocity. So at best this information can weakly constrain $\alpha$, and in the case of the Bullet Cluster the X-ray shock inferred velocity is significantly greater than the free-fall velocity, $v_{3D_{max}}$, thus it provides no additional constraining power. In Section 3.1 I discuss how the results of this method can be used in conjunction with N-body simulations to limit the computational impact of accounting for the uncertainty in $\alpha$.

3.2.2. Added Temporal Prior

One of the advantages of this Monte Carlo method is that additional constraints are easily incorporated ex post facto. An example of such constraints in the case of the Bullet Cluster is the observed X-ray shock front and factor of 2.4 greater X-ray estimated mass to lensing estimated mass (Markevitch 2006), due to merger-related X-ray temperature and luminosity boost. Hydrodynamical simulations of merging clusters (e.g., Ricker & Sarazin 2001; Randall et al. 2002) suggest that such transient effects last of order the X-ray sound crossing time. Since simulations show negligible difference between the timescales of the two I chose to construct a prior based on the observed temperature boost. Randall et al. (2002) find that the FWHM duration of the temperature boost is $\sim 0.4 t_{sc}$ with the entire boost duration being $\sim 1.4 t_{sc}$, where $t_{sc}$ is the sound crossing time of the more massive of the two subclusters. The peak of this boost roughly coincides with the time of the collision, as defined in Section 1. Given the $M_{200} = 15 \times 10^{14} M_\odot$ and temperature $T_X = 14$ keV of the “main” subcluster (Markevitch 2006), the $t_{sc} = 1$ Gyr. I construct a sigmoid function for the TSC prior PDF based on the observed temperature boost,

$$PDF(TSC) = \frac{1}{2} \left[ 1 - \tanh \left( \frac{TSC - 0.5a}{0.25b} \right) \right],$$

where $a$ is the FWHM of the duration of the temperature boost and $b$ is the entire boost duration. I chose a sigmoid function over a simple step function since the temperature boost predicted by Randall et al. (2002) does not end abruptly. This prior is coupled with the previously discussed TSC prior (Equation (5)).

Application of this prior significantly improves the uncertainty in $TSC_0$ (180% to 67%) and $v_{3D}(t_{col})$ (28% to 19%), compare Figure 3 with Figure 4. It essentially removes the possibility of a TSC > 0.6 Gyr. As expected from the $\alpha$ dependence shown by the green triangles in Figure 3 this prior also reduces the likelihood of $\alpha > 50$ deg, which in turn affects both the location and uncertainty of $d_{3D}$ and $v_{3D}(t_{obs})$; see Table 2. The remaining parameter estimates are predominantly unaffected by the prior, with only a few having their confidence limits affected as the result of their high-end low-probability tails being down weighted. Additionally there is now essentially zero probability that the bullet subcluster has reached the apoaips and is on a return trajectory, since the 95% lower confidence limit of TSC1 is 0.9 Gyr (see Table 2) and the prior essentially removes the possibility of a TSC > 0.6 Gyr. I present the full results array, which includes the default analysis prior combined with this temperature boost prior, in Appendix C and the compact parameter estimates in Table 2.

According to this analysis the Springel & Farrar (2007) results stated in Section 2.3 seem unlikely (see the black diamond of Figure 4); however, this is simply due to their definition of the “observed state.” They define the observed state to be when their simulated X-ray properties most closely match the observed X-ray properties, yet the separation of the halos in this state is only $d_{3D} = 625$ kpc; this is less than the observed $d_{proj} = 720 \pm 25$ kpc (Bradač et al. 2006). If we instead consider their estimate of $TSC_0$ for $d_{3D}$ between 700 and 900 kpc (corresponding to $d_{proj} = 700$ and 0 deg $< \alpha < 35$ deg), then $0.24 < TSC_0 < 0.33$ Gyr (see green bar of Figure 4). This brings their result in line with the results of this method, as expected by the agreement presented in Section 2.3. Note that the general conclusion of Springel & Farrar (2007), that the shock speed greatly overestimates the actual relative speed of the subclusters, remains valid regardless of which “observed state” is used.

4. MUSKET BALL CLUSTER DYNAMICS

I also apply the method to the Musket Ball Cluster, with the objective of updating an existing analysis and comparing this system with the Bullet Cluster. A preliminary analysis of the system dynamics using a similar method (Dawson et al. 2012) suggested that the Musket Ball Cluster merger is $\sim 3$–5 times further progressed than other confirmed dissociative mergers. However, that analysis treated the two merging subclusters as uniform density spheres and also failed to account for the temporal phase-space PDF (Equation (5)). Additionally the claim that the Musket Ball Cluster is both slower and further progressed than the Bullet Cluster was based on comparing the Musket Ball’s TSC0–$v_{3D}(t_{col})$ PDF with that of the single point Springel & Farrar (2007) estimate. As noted in Section 3.2.1 there is a large area of parameter space that the Springel & Farrar (2007) result fails to represent.

Similar to my analysis of the Bullet Cluster I perform the analysis with 2,000,000 Monte Carlo realizations. Parameter estimates converge to better than a fraction of a percent with only 20,000 realizations.

4.1. Musket Ball Observed System Properties

I show the observed Musket Ball Cluster parameter PDFs in Figures 5–7, each the result of analyses presented by Dawson et al. (2012). I refer to their “south” subcluster as halo 1 and “north” subcluster as halo 2. The mass PDFs, Figure 5, are the result of an MCMC analysis where NFW halos were simultaneously fit to the weak lensing signal. The relative velocity distributions, Figure 6, are the result of a bootstrap error analysis (Beers et al. 1990) of the 38 and 35 spectroscopic members of the north and south subclusters, respectively. These redshifts as well as the full Musket Ball Cluster spectroscopic catalog are presented in Table 4 of Appendix B. The projected subcluster separation distribution, Figure 7, is the result of a bootstrap error analysis of the recursively estimated subclusters’ galaxy number density centroids (see, e.g., Randall et al. 2008, for a description of this method). For each Monte Carlo realization individual values are drawn randomly from each of these distributions.
This more complete analysis confirms that the Musket Ball Cluster merger is both significantly slower and further progressed compared to the Bullet Cluster; see Figure 8. To estimate a lower limit on how much further it progressed I perform an additional Monte Carlo analysis for TSC0Bullet − TSC0Musket, assuming the marginalized TSC0 distributions (see Appendices C and D). This is a lower limit since the Musket Ball observations, unlike the Bullet Clusters observations, cannot rule out the case that its subclusters have reached the apoapsis and are on a return trajectory (61% of the realizations have TSC1 less than the age of the universe at z = 0.53). I find that the Musket Ball is at least 0.8±0.4 Gyr (3.4±3.8 times) further progressed than the Bullet Cluster; see Figure 9. This is in line with the more approximate 3–5 times estimate of Dawson et al. (2012). The Musket Ball’s relatively large TSC0 means that it has potential for providing tighter constraints on σDM, since the expected offset between the galaxies and dark matter will initially increase with increasing TSC0. However, as noted in Section 1, given enough time the expected offset will decrease due to the gravitational attraction between the galaxies and dark matter. Also important in determining which cluster can provide the tightest σDM constraints is the fact that the expected offset increases as a function of the cluster surface mass density and collision velocity, both of which are larger in the case of the Bullet Cluster (compare Tables 2 and 3). Without running SIDM simulations it is difficult to know at what TSC0 the offset reaches it maximum, or which merger parameters are most important for maximizing the offset. The complete Musket Ball Cluster parameter estimates are summarized in Table 3 and plotted in Appendix D.

Note that just as a temporal prior was justified for the Bullet Cluster based on the observed shock front and increased temperature/mass estimate, I could apply a similar yet opposite prior to the Musket Ball since the temperature/mass estimate is consistent with the weak lensing inferred mass (additionally no shock front is observed). According to Randall et al. (2002) if the cluster mass and inferred X-ray temperature or luminosity cluster mass are approximately the same, then TSC0 ≳ 2τsc, which in the case of the Musket Ball means TSC0 ≳ 1.75 Gyr. While this is consistent with my TSC0 estimate for the Musket Ball, it is not entirely appropriate to apply this prior since the X-ray observations are relatively shallow and cannot confidently rule out a temperature and luminosity boost (Dawson et al. 2012). However, it is conceivable that this line of reasoning would be applicable with deeper X-ray observations, for either the Musket Ball or similar dissipative mergers.

### 4.2. Musket Ball System Dynamics Results

The Astrophysical Journal, 772:131 (19pp), 2013 August 1

**Table 2**

Bullet Cluster Parameter Estimates

| Parameter | Units | Default Priors | Default + Added Temporal Priors |
|-----------|-------|----------------|-------------------------------|
| M200 | 10¹⁴ M⊙ | Location⁴ | 68% LCL–UCL⁵ | 95% LCL–UCL⁵ |
|         |       | Location⁴ | 68% LCL–UCL⁵ | 95% LCL–UCL⁵ |
| z₁ | Gyr | 1.2 | 1.0–2.4 | 0.9–8.2 |
| z₂ | Gyr | 1.3 | 1.1–2.5 | 1.0–4.6 |
| dproj | Mpc | 0.72 | 0.69–0.76 | 0.56–0.80 |
| σ | deg | 50 | 27–73 | 15–84 |
| α | Mpc | 1.1 | 0.8–2.6 | 0.7–7.1 |
| δmax | Mpc | 1.3 | 1.1–2.5 | 1.0–4.6 |
| vproj | km s⁻¹ | 820 | 640–1500 | 550–2500 |
| v3D | km s⁻¹ | 3000 | 2700–3800 | 2500–4200 |
| TSC0 | Gyr | 0.6 | 0.3–1.1 | 0.2–3.9 |
| TSC1 | Gyr | 1.2 | 1.0–2.4 | 0.9–8.2 |
| T | Gyr | 1.3 | 1.5–3.2 | 1.4–8.1 |

**Notes.**

⁴ Biweight-statistic location (see, e.g., Beers et al. 1990).
⁵ Bias-corrected lower and upper confidence limits, LCL and UCL, respectively (see, e.g., Beers et al. 1990).

This summary and discussion I have introduced a new method for determining the dynamic properties and associated uncertainty of dissipative cluster mergers given only the most general merger observables: mass

**Table 3**

Musket Ball Cluster Parameter Estimates

| Parameter | Units | Location⁴ | 68% LCL–UCL⁵ | 95% LCL–UCL⁵ |
|-----------|-------|------------|----------------|----------------|
| M200 | 10¹⁴ M⊙ | 2.3–4.3 | 1.6–5.5 |
| M200 | 10¹⁴ M⊙ | 1.1–2.4 | 0.6–3.3 |
| z₁ | 0.5339 | 0.5333–0.5345 | 0.5326–0.5352 |
| z₂ | 0.5316 | 0.5305–0.5324 | 0.5294–0.5331 |
| dproj | Mpc | 1.0 | 0.9–1.1 | 0.7–1.3 |
| α | deg | 48 | 28–67 | 13–78 |
| α | Mpc | 1.6 | 1.2–2.9 | 0.9–5.5 |
| δmax | Mpc | 2.1 | 1.5–3.8 | 1.1–7.3 |
| vproj | km s⁻¹ | 670 | 390–1100 | 140–1500 |
| v3D | km s⁻¹ | 2300 | 2000–2500 | 1800–2800 |
| TSC0 | Gyr | 1.1 | 0.7–2.4 | 0.5–5.8 |
| TSC1 | Gyr | 3.5 | 2.0–7.2 | 1.4–12.0 |
| T | Gyr | 4.8 | 2.9–10.4 | 2.2–22.7 |

**Notes.**

⁴ Biweight-statistic location (see, e.g., Beers et al. 1990).
⁵ Bias-corrected lower and upper confidence limits, LCL and UCL, respectively (see, e.g., Beers et al. 1990).

61% of the realizations with a valid TSC1 (i.e., less than the age of the universe at the cluster redshift) have a valid TSC1, meaning that it is possible that the Musket Ball Cluster is being observed in the “incoming” state.

### 5. SUMMARY AND DISCUSSION

I have introduced a new method for determining the dynamic properties and associated uncertainty of dissipative cluster mergers given only the most general merger observables: mass
of each subcluster, redshift of each subcluster, and projected separation of the subclusters. I find that this method addresses the primary weaknesses of existing methods, namely enabling accurate parameter estimation and propagation of uncertainty near the collision state with a convergent solution achieved in \( \sim 6 \) CPU hours. I have confirmed that the two-NFW-halo model is capable of achieving the required 10\% level accuracy by direct comparison with an \( N \)-body hydrodynamic simulation.

In applying this method to the Bullet Cluster I not only determined its merger dynamic parameters but found that the bulk of uncertainty in these parameters is due to uncertainty in \( \alpha \), the angle of the merger with respect to the plane of the sky. Analyses that fail to account for the uncertainty in \( \alpha \) (all existing \( N \)-body simulations of the Bullet Cluster) will significantly underestimate the uncertainty in their results. This highlights the need to carefully select and model many possible realizations of the merger when trying to infer results from \( N \)-body simulations of a real merger (I discuss this further in Section 5.1). I have also shown how ex post facto priors can easily be applied to the results of the default priors to further constrain the inferred dynamic properties. In particular accurate measurement of the cluster gas properties can enable approximately a factor of two better constraint on the dynamic properties of the merger, principally through added constraint on the timescale of the merger.

I have also applied this method to the Musket Ball Cluster, validating the approximate results of Dawson et al. (2012). Comparing the dynamic properties of the Musket Ball with those of the Bullet I have shown that the Musket Ball represents a significantly different volume of merger phase space. The Musket Ball Cluster, being \( 3.4^{+3.4}_{-1.4} \) times further progressed than the Bullet Cluster, could potentially provide tighter constraints on \( \sigma_{\text{DM}} \) since the offset between galaxies and dark matter should initially increase with time post-merger for \( \sigma_{\text{DM}} > 0 \). And the larger the expected offset, the better the dark matter constraint when applying a method similar to Randall et al. (2008).

### 5.1. Suggested Uses of Method

While a general method for determining the dynamics properties of merging clusters has numerous applications, several are worth noting. As noted \( N \)-body simulations of specific merging clusters are computationally expensive; in particular one SIDM simulation of a single dissociative merger requires \( \sim 1-10 \) million CPU hours (J. Bullock 2012, private communication). Thus, it is currently unfeasible to simulate all confirmed dissociative mergers. This method can be used to quickly determine which mergers provide the best \( \sigma_{\text{DM}} \) constraining power, enabling an efficient use of limited computational resources.

Additionally it is inappropriate to simply simulate one realization of a dissociative merger due to the broad range of merger phase space allowed by uncertainty in observed parameters, as discussed in detail in Section 3.2.1. Thus, multiple simulations of each merger are required to properly represent the allowed phase space. One could conceivably reduce the number of required simulations by using the results of this method to select representative merger realizations that uniformly sample the merger phase space of interest (e.g., cluster mass, \( v_{\text{3D}}(t_{\text{col}}) \), and TSC\(_0\)) and then weight the results of each simulated realization by the integral of the corresponding local phase space PDF, as determined by this method. For example, one could estimate the uncertainty distribution of the \( \sigma_{\text{DM}} \) constraint inferred from SIDM simulations of the Bullet Cluster by weighting the constraint from each realization, where a realization with \( v_{\text{3D}}(t_{\text{col}}) = 2800 \) km s\(^{-1}\) and TSC\(_0\) = 0.4 Gyr would receive greater weight than one with \( v_{\text{3D}}(t_{\text{col}}) = 4000 \) km s\(^{-1}\) and TSC\(_0\) = 0.2 Gyr; see Figure 4. Thus, the results of this method not only will inform efficient selection of realizations to model but will reduce the number of simulations required to properly sample the posterior PDFs. Nevertheless, SIDM simulations of mock clusters need to be performed to determine how much acceptable values of \( \sigma_{\text{DM}} \) affect the inferred merger dynamic properties.

General merger dynamic properties are also important for understanding how cluster mergers relate to other physical phenomena, such as galaxy evolution and radio relics. It is well established that galaxy clusters play an important role in the evolution of their member galaxies, but it is still unclear whether cluster mergers trigger star formation (e.g., Miller & Owen 2003; Owen et al. 2005; Ferrari et al. 2005; Hwang & Lee 2009), quench it (Poggianti et al. 2004), or have no immediate effect (Chung et al. 2010). Studying mergers at different TSC may resolve these seemingly conflicting results by discriminating between slow-working processes (e.g., galaxy harassment or strangulation) and fast-acting process (e.g., ram pressure stripping). Similarly, studying global merger dynamic properties may resolve the mystery of why many mergers have associated radio relics (e.g., Barrena et al. 2009; van Weeren et al. 2011) yet others do not (e.g., Russell et al. 2011).

### 5.2. Extensions to the Method

While this method has advantages over existing methods, there is room for considerable improvement. For example the method could be improved through the elimination of some of the simplifying assumptions of the model (see Section 2.1). One could attempt to incorporate subcluster mass accretion physics in a manner similar to the work of Angus & McGaugh (2008) or attempt to account for the possibility of a non-zero impact parameter. To incorporate the latter one must (1) add angular momentum terms to the equations of motion, which is entirely feasible, and (2) prescribe a reasonable impact parameter prior. Randall et al. (2002) nicely outline how to determine an impact parameter PDF for halo mergers of variable mass by utilizing the PDF of the dimensionless spin parameter, determined from linear theory of the growth of structure (Peebles 1993) and simulations (Bullock et al. 2004). However, this prior should be adjusted to account for the amount of gas dissociated during the observed merger, since this amount will decrease as the impact parameter increases. Without a systematic study of various mergers in hydrodynamic simulations it is unclear exactly what adjustment an observed large dissociation of gas should infer.

Another significant extension to the model could be the inclusion of SIDM physics. As mentioned in the previous section, one of the promising uses of this method is to suggest which mergers might provide the best \( \sigma_{\text{DM}} \) constraining power. However, one could take this a step further by including an analytic treatment of SIDM physics (e.g., Markovich et al. 2004), thereby enabling analytic estimates of \( \sigma_{\text{DM}} \) relevant effects for a given merger. Then this method could be used in conjunction with observed dissociative mergers to place direct constraints on \( \sigma_{\text{DM}} \). Due to the increased complexity of the physics involved it would be necessary to verify this extension with SIDM \( N \)-body simulations.

I thank my adviser David Wittman, who has always encouraged my research-freewill, while at the same time providing invaluable input and correcting guidance. Our many fruitful
discussions have touched every aspect of this work. I also thank the Deep Lens Survey—in particular Perry Gee—for access to the 2007 Keck LRIS spectra, as well as Perry Gee and Brian Lemaux for assistance in reduction of the 2011 Keck DEIMOS spectra. I am grateful to Jack P. Hughes for discussions on constraining the Bullet Cluster’s TSC by the observed X-ray shock feature and boosted temperature/luminosity, and Reinout J. van Weeren for discussions on the possibilities of constraining the dynamics and geometry of mergers using radio relics. Finally I would like to thank Maruša Bradaˇc, Ami Choi, James Jee, Phil Marshall, Annika Peter, Michael Schneider, Reinout van Weeren, and David Wittman for their substantial reviews of earlier drafts.

Support for this work was provided by NASA through Chandra Award Number GOI-12171X issued by CXO Center, which is operated by the SDO for and on behalf of NASA under contract NAS8-03060. Support for program number GO-12377 was provided by NASA through a grant from STScI, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS5-26555. Support for this work was also provided by Graduate Research Fellowships through the University of California, Davis. I would also like to acknowledge the sultry universe who hides her secrets well.

Note added in proof. W. Dawson has made Python code implementing the discussed Monte Carlo method openly available at git://github.com/MCTwo/MCMAC.git. He has also made all supporting work to this paper openly available at git://github.com/wadawson/merging-cluster-dynamics-paper.git.

APPENDIX A

POTENTIAL ENERGY OF TWO TRUNCATED NFW HALOS

Generically the potential energy of a two-halo system with center-to-center separation \( r \) is

\[
V(r) = \int \Phi_1(r') dm_z, \tag{A1}
\]

where \( \Phi_1(r') \) is the gravitational potential of halo 1 as a function of radial distance \( r' \) from the center of the halo 1 to the mass element of halo 2, \( dm_z \). I derive \( \Phi_1(r') \) for the case of a truncated NFW halo in Appendix A.1. The integral of Equation (A1) can be approximated as a summation over \( N \) \( \times N \) mass elements, \( m_{z_{ij}} \), each with area \( dr \times d\theta \), where \( i \) and \( j \) range from 0 to \( N-1 \),

\[
V(r) \approx \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} \Phi_1(r'_{ij} + \epsilon) m_{z_{ij}},
\]

where \( r'_{ij} \) is the distance from the center of halo 1 to the second halo’s mass element \( m_{z_{ij}} \), as derived in Appendix A.2, and \( \epsilon \) is the softening length which reduces the effects of artificial singularities.

A.1. Truncated NFW Gravitational Potential

For an axially symmetric mass distribution the potential can be expressed as a series of Legendre Polynomials

\[
\Phi_{\rho}(r) = -\frac{2\pi G}{n + 1/2} \int_0^r r^{n+2} \rho_\rho(r') \, dr', \tag{A2}
\]

where

\[
\rho_\rho(r) = (n + 1/2) \int_0^r \rho(r', \theta) P_n(\cos \theta) \sin \theta \, d\theta. \tag{A3}
\]

Assuming a spherical NFW halo

\[
\rho_{NFW}(r) = \frac{\rho_s}{r/r_s(1 + r/r_s)^2}
\]

only the zeroth order term of Equation (A3) remains

\[ \rho_{NFW}(r) = \rho_0(r) \]

and Equation (A2) reduces to

\[
\Phi_{NFW}(r) = -\frac{4\pi G}{r} \int_0^r r'^2 \rho_{NFW}(r') \, dr' - 4\pi G \int_r^\infty r' \rho_{NFW}(r') \, dr',
\]

\[
\Phi_{NFW}(r) = -\frac{4\pi G \rho_s}{r} \left[ \int_0^r r'^2 \left( \frac{r'}{r_s(1 + r/r_s)^2} \right) \, dr' + r \int_r^\infty \frac{r'}{r_s(1 + r/r_s)^2} \, dr' \right].
\]

Since I truncate the NFW halo at \( r_{200} \) the \( \infty \) in the second integral becomes \( r_{200} \) and

\[
\Phi_{NFW_i}(r) = -\frac{4\pi G \rho_s r_s}{G r_{200}} \left[ \ln(1 + r/r_s) - \frac{r}{r_{200}} \right], \quad \text{if } r \leq r_{200}; \quad \text{if } r > r_{200}. \tag{A4}
\]

A.2. Mass Elements of a Truncated NFW Halo

Given the differential mass elements for a spherically symmetric halo

\[
dm = 2\pi \rho(r, \theta) r^2 \sin(\theta) d\theta \, dr,
\]

and discretizing the mass into elements with lengths \( \delta r = r_{200}/N \) and \( \delta \theta = \pi/N \) the halo 2 mass elements are given by

\[
m_{ij} = 2\pi \int_{r_{ij}}^{r_{ij+1}} \int_{\theta_{ij}}^{\theta_{ij+1}} \rho(r') r'^2 \sin(\theta') d\theta' \, dr'.
\]

For an NFW halo this becomes

\[
m_{ij} = 2\pi \rho_s r_s^3 [\cos(j \delta \theta) - \cos((j + 1)\delta \theta)]
\]

\[
\times \left[ \left( 1 + \frac{(i + 1) \delta r}{r_s} \right)^{-1} - \left( 1 + \frac{i \delta r}{r_s} \right)^{-1} \right]
\]

\[
+ \ln \left[ \frac{(i + 1) \delta r + r_s}{i \delta r + r_s} \right].
\]

(This table is available in its entirety in a machine-readable form in the online journal. A portion is shown here for guidance regarding its form and content.)

APPENDIX B
MUSKET BALL CLUSTER REDSHIFT CATALOG

The Musket Ball Cluster redshift catalog (Table 4) contains 738 spectroscopically confirmed galaxy redshifts. The galaxies are within an $\sim 18' \times 18'$ area centered on the Musket Ball Cluster (139.05 deg, +29.85 deg). The sources of the redshifts are from three separate spectroscopic surveys: (1) LRIS 2007 was carried out on 2007 January 15 using the Keck: I LRIS instrument, (2) DEIMOS 2011A was carried out on 2011 March 1 and 2 using the Keck: II DEIMOS instrument, and (3) DEIMOS 2012B was carried out on 2013 January 16 using the Keck: II DEIMOS instrument.

The DEIMOS 2011A observations consisted of six slit masks with 1'' slits and using the 1200 line mm$^{-1}$ grating, tilted to a central wavelength of 6700 Å, resulting in a pixel scale of 0.33 Å pixel$^{-1}$, a resolution of $\sim 1.1$ Å (50 km s$^{-1}$), and typical wavelength coverage of 5400 Å to 8000 Å. The DEIMOS 2013B observations consisted of 1 slit mask with 1'' slits and using the 1200 line mm$^{-1}$ grating, tilted to a central wavelength of 6200 Å, resulting in a pixel scale of 0.33 Å pixel$^{-1}$, a resolution of $\sim 1$ Å (50 km s$^{-1}$), and typical wavelength coverage of 4900 Å to 7500 Å. The exposures for each DEIMOS mask ($\sim 3 \times 20$ minutes) were combined using the DEEP2 version of the spec2d package (Newman et al. 2012). This package combines the individual exposures of the slit mosaic and performs wavelength calibration, cosmic ray removal, and sky subtraction on a slit-by-slit basis, generating a processed two-dimensional spectrum for each slit. The spec2d pipeline also generates a processed one-dimensional spectrum for each slit. This extraction creates a one-dimensional spectrum of the target, containing the summed flux at each wavelength in an optimized window. Table 4 only includes high-quality ($Q \geq 3$; see Newman et al. 2012 for an explanation on the quality codes) galaxy spectra. Details of the LRIS 2007 observations and reduction are discussed in the Deep Lens Survey data release paper (D. Wittman et al., in preparation).

APPENDIX C
BULLET CLUSTER RESULT PLOTS

This section contains the parameter results array plots for the Bullet Cluster case including the added temporal prior of Section 3.2.2. For ease of display the added temporal prior is grouped in three categories (Input, Geometry, and Velocity & Time), resulting in a six subplot results array (see Figure 10). The six subplots of the Bullet Cluster results array are shown in Figures 11–16. The Input parameters consist of $M_{200}$, $M_{200}$, $z_1$, $z_2$, and $d_{200}$. The calculated Geometry parameters consist of $\alpha$, $d_{3D}$, and $d_{max}$. The calculated Velocity & Time parameters consist of $v_{3D}(t_{obs})$, $v_{3D}(t_{col})$, TSC0, TSC1, and $T$. (A color version of this figure is available in the online journal.)

The calculated Geometry parameters consist of $\alpha$, $d_{3D}$, and $d_{max}$. The calculated Velocity & Time parameters consist of $v_{3D}(t_{obs})$, $v_{3D}(t_{col})$, TSC0, TSC1, and $T$.

APPENDIX D
MUSKET BALL CLUSTER RESULT PLOTS

This section contains the parameter results array plots for the Musket Ball Cluster (Figures 17–22). Similar to Appendix C, the parameters are grouped in three categories (Input, Geometry, and Velocity & Time), resulting in a six subplot results array (see Figure 10). The Input parameters consist of: $M_{200}$, $M_{200}$, $z_1$, $z_2$, and $d_{200}$, where halo 1 refers to the “main” subcluster and halo 2 refers to the “bullet” subcluster. The Geometry parameters consist of the randomly drawn $\alpha$ and calculated $d_{3D}$ and $d_{max}$. The calculated Velocity & Time parameters consist of TSC0, TSC1, and $T$. (A color version of this figure is available in the online journal.)
Figure 11. Bullet Cluster marginalized Input vs. Input parameters result plots, for the case including the added temporal prior of Section 3.2.2. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively. The black dashed line is the biweight-statistic location (Beers et al. 1982).

(A color version of this figure is available in the online journal.)

Figure 12. Bullet Cluster marginalized Input vs. Geometry parameters result plots, for the case including the added temporal prior of Section 3.2.2. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively.

(A color version of this figure is available in the online journal.)
Figure 13. Bullet Cluster marginalized Input vs. Velocity & Time parameters result plots, for the case including the added temporal prior of Section 3.2.2. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively.

(A color version of this figure is available in the online journal.)

Figure 14. Bullet Cluster marginalized Geometry vs. Geometry parameters result plots, for the case including the added temporal prior of Section 3.2.2. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively. The black dashed line is the biweight-statistic location (Beers et al. 1982).

(A color version of this figure is available in the online journal.)
Figure 15. Bullet Cluster marginalized Geometry vs. Velocity & Time parameters result plots, for the case including the added temporal prior of Section 3.2.2. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively.

(A color version of this figure is available in the online journal.)
Figure 16. Bullet Cluster marginalized $Velocity \& Time$ vs. $Velocity \& Time$ parameters result plots, for the case including the added temporal prior of Section 3.2.2. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively. The black dashed line is the biweight-statistic location (Beers et al. 1982). (A color version of this figure is available in the online journal.)

Figure 17. Musket Ball Cluster marginalized $Input$ vs. $Input$ parameters result plots. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively. The black dashed line is the biweight-statistic location (Beers et al. 1982). (A color version of this figure is available in the online journal.)
**Figure 18.** Musket Ball Cluster marginalized $Input$ vs. $Geometry$ parameters result plots. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively. (A color version of this figure is available in the online journal.)

**Figure 19.** Musket Ball Cluster marginalized $Input$ vs. $Velocity$ & $Time$ parameters result plots. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively. (A color version of this figure is available in the online journal.)
Figure 20. Musket Ball Cluster marginalized Geometry vs. Geometry parameters result plots. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively. The black dashed line is the biweight-statistic location (Beers et al. 1982).

(A color version of this figure is available in the online journal.)

Figure 21. Musket Ball Cluster marginalized Geometry vs. Velocity & Time parameters result plots. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively.

(A color version of this figure is available in the online journal.)
Figure 22. Musket Ball Cluster marginalized Velocity & Time vs. Velocity & Time parameters result plots. Dark and light blue colors correspond to 68% and 95% confidence intervals, respectively. The black dashed line is the biweight-statistic location (Beers et al. 1982).

(A color version of this figure is available in the online journal.)
