(Dated: February 2, 2008)

Alanates and boranates are studied intensively because of their potential use as hydrogen storage materials. In this paper we present a first-principles study of the electronic structure and the energetics of beryllium boranate, Be(BH$_4$)$_2$. From total energy calculations we show that in contrast to the other boranates and alanates - hydrogen desorption directly to the elements is likely, and is at least competitive with desorption to the elemental hydride (BeH$_2$). The formation enthalpy of Be(BH$_4$)$_2$ is only $-0.12 \text{ eV/H}_2$ (at $T = 0 \text{K}$). This low value can be rationalized by the participation of all atoms in the covalent bonding, in contrast to the ionic bonding observed in other boranates. From calculations of thermodynamic properties at finite temperature we estimate a decomposition temperature of 162 K at a pressure of 1 bar.

I. INTRODUCTION

In the last decade the environmental importance of reducing the CO$_2$ exhaust has been widely accepted. The use of hydrogen based fuel cells is an important contribution to achieve this reduction. One major obstacle for this use is the development of a method for hydrogen storage with a high gravimetric and volumetric hydrogen density.\(^1\)

One way of storing hydrogen is in a (complex) metal hydride. The ideal hydrogen storage material should have the highest possible gravimetric hydrogen density. This obviously requires the use of lightweight materials. Moreover, the formation energy of the hydride has to be such that it is stable at atmospheric conditions, yet it has to decompose at a moderate temperature to release the hydrogen. A further important point is that the reactions involved in hydrogen de/absorption must have fast kinetics.

Over the last decade alanates and boranates have been studied extensively as potential hydrogen storage materials.\(^2,3\) Alanates and boranates consist of a lattice of metal cations and (AlH$_4$)$^-$ or (BH$_4$)$^-$ complex anions, respectively. Generally these materials decompose by heating via intermediate complex hydrides into bulk metals, elemental hydrides and hydrogen gas. In the last few years the attention has gradually shifted from alanates towards boranates, because of the high gravimetric hydrogen density in the latter. Many boranates turn out to be too stable, however.

In principle a large variety of boranates can be synthesized by changing the metal cations, which can be used to tune the formation energy.\(^4,5,6,7,8,9,10\) So far most effort has been devoted to the alkalai boranates and more recently to mixtures of alkalai boranates and to the alkaline earth boranates.\(^11,12\) In order to understand the chemical trends we have recently developed a simple model for the formation energies of these compounds.\(^18\) This model demonstrates that these boranates are ionic compounds (in the sense discussed above) and that the difference in their formation energies can be understood on the basis of the electrostatic (Madelung) lattice energy. The basic stability of the (BH$_4$)$^-\text{cation}$ is not affected by substituting one alkali or alkaline earth cation by another.

The stability of (BH$_4$)$^-$ may be changed by adding an element that competes with boron in binding with hydrogen. To investigate this possibility we study beryllium boranate, Be(BH$_4$)$_2$, in this paper. Establishing the electronic structure and thermodynamic stability of Be(BH$_4$)$_2$ will assist in understanding the chemical and physical trends in alkali, alkaline earth alanates and boranates.\(^19\)

We present a first principles study of the electronic structure and the thermodynamic properties of Be(BH$_4$)$_2$. The electronic structure in relation to the crystal structure is used to analyze the bonding in Be(BH$_4$)$_2$. We calculate total energies and phonon frequencies of all compounds involved in possible formation reactions of Be(BH$_4$)$_2$. From these data we obtain the thermodynamic properties at finite temperature.

II. COMPUTATIONAL METHODS

First-principles calculations are carried out within the density functional theory (DFT) approach, applying a generalized gradient approximation (GGA) for the exchange correlation functional.\(^21\) We use a plane wave basis set and the projector augmented wave (PAW) method\(^22,23\) as implemented in the Vienna Ab initio Simulation Package (VASP)\(^24,25,26\) and apply non-linear
core corrections.27

Brillouin zone integrations are performed with a tetrahedron method28 for calculating total energies. A Gaussian smearing method is used for calculating densities of states, with a smearing parameter of 0.1 eV. The k-point meshes are such that total energies are converged within 0.1 meV per formula unit. The total energies used in the calculations of the reaction enthalpies are calculated with a high plane wave kinetic energy cutoff of 700 eV. By varying the computational parameters, in particular by trying different PAW potentials,29 we estimate that reaction enthalpies are converged on a scale of 5 meV.

The atomic positions and lattice parameters are relaxed using a conjugate gradient algorithm for a range of fixed volumes. The total energy versus volume curve obtained this way is fitted with a Murnaghan’s equation of state expression, which yields the ground state volume, the bulk modulus, and its pressure derivative.30 At the ground state volume we relaxed the atomic positions and lattice parameters to obtain the ground state structure. This procedure is followed for all compounds mentioned in this paper.

To calculate the zero point energies (ZPE) and phonon densities of state we need the phonon frequencies of all these compounds. Vibrational frequencies are obtained from the dynamical matrix, whose matrix elements (the force constants) are calculated using a finite difference method.31 The force constants are calculated from displacements of 0.005 Å in two opposite directions for each atomic degree of freedom. For both bulk beryllium and beryllium hydride 2 × 2 × 2 supercells give converged ZPEs. One does not need a supercell to calculate the phonon frequencies of Be(BH₄)₂, since the unit cell of Be(BH₄)₂ is sufficiently large. For boron we use the frequencies that have been reported earlier.32

III. CRYSTAL STRUCTURE

Be(BH₄)₂ can be synthesized by the reaction of lithium boranate and beryllium chloride. Its crystal structure consists of helical polymers of alternating beryllium and boron atoms (Bₓ) that are connected via pairs of hydrogen atoms (Hₓ).33 The crystal structure is given in Figure 2. A further boron atom (Bₓ) is attached to each beryllium atom, again via a pair of dangling hydrogen atoms (Hₓ). The polymers are packed in the crystal structure as shown in Figure 2. On the basis of this structure one may expect a strong bonding between the atoms in one polymer chain, and a much weaker bonding between the polymer chains. The latter is reflected in the low melting point of Be(BH₄)₂ of 125°C.

We relaxed the crystal structure of Be(BH₄)₂ as described in the previous section, including the cell volume, lattice parameters and atomic positions, while keeping the experimental space-group and Wyckoff positions.

**FIG. 1:** Schematic bonding scheme and labeling of the atoms within a polymer chain in Be(BH₄)₂. The three dimensional structure is given in Fig. 2. The numbers indicate optimized bond lengths in Å.

![Crystal structure](image2)

**FIG. 2:** (Color online) Crystal structure of Be(BH₄)₂.

Except for the cell volume, the parameters compare well to the experimental values.33 The calculated cell volume is 15% larger than the experimental cell. This indicates that the binding between the polymer chains is indeed weak and of van der Waals type. It is well-known that, using the common functionals, DFT fails to capture van der Waals bonding. However, the total energy difference between the experimental and calculated cell volumes is less than 5 meV/H₂. This error only has a minor effect on the relative total energies.

The optimized B–H and Be–H bond lengths are given in Fig. 1. As references, the B–H bond length in a (BH₄)⁻ anion is 1.21 Å, whereas a B–H bond length in a typical three center B–H–B bond is 1.34 Å.34 Comparison with these numbers indicates that the B–H bonding in Be(BH₄)₂ is closer to that in the (BH₄)⁻, although there is some distortion due to the presence of the Be atom, in particular on the Bₓ–Hₓ bond. This could indicate some competition between B and Be for bonding.

IV. ELECTRONIC STRUCTURE

As discussed above the crystal structure of Be(BH$_4$)$_2$ indicates a weak bonding between polymer chains, and a stronger bonding within a polymer chain. The charge displacement upon bond formation can be visualized by...

to hydrogen. For comparison, the B–H bond lengths in alkali boranates are all very close to 1.21 Å. The Be–H bond lengths are still quite large, however, which indicates a significant ionic contribution to the bonding.

We have also optimized the structure of BeH$_2$, see Table II. It agrees well with the experimental structure$^{32}$ and with that obtained in a previous calculation$^{37}$, the largest difference being that our calculated bulk modulus (21.4 GPa) is $\sim 10 \%$ smaller than that calculated in Ref. 37 (23.8 GPa). For elemental boron we use the $\beta$-

To hydrogen. For comparison, the B–H bond lengths in alkali boranates are all very close to 1.21 Å. The Be–H bond lengths are still quite large, however, which indicates a significant ionic contribution to the bonding.

We have also optimized the structure of BeH$_2$, see Table II. It agrees well with the experimental structure$^{32}$ and with that obtained in a previous calculation$^{37}$, the largest difference being that our calculated bulk modulus (21.4 GPa) is $\sim 10 \%$ smaller than that calculated in Ref. 37 (23.8 GPa). For elemental boron we use the $\beta$-
plotting the charge density difference, i.e. the charge density of Be(BH$_4$)$_2$ minus that of the individual isolated atoms. Cuts through the charge density difference in various planes along a polymer backbone are shown in Fig. 4. They clearly indicate the formation of B–H covalent bonds, which are polarized somewhat towards the H atoms. The character of the Be–H bonds is much less clear from these plots. In any case these bonds are strongly polarized in the direction of the H atoms.

The electronic projected density of states (PDOS) of Be(BH$_4$)$_2$, projected on s, p components of the individual atoms, is shown in Fig. 5. Tetrahedrally bonded BH$_4^-$ generates a characteristic pattern in the valence band part of the PDOS, which is qualitatively similar to that observed for AlH$_4^-$ tetrahedra in the alanates. The tetrahedral geometry of BH$_4^-$ results in a splitting into two valence peaks, the lower one of s (A$_1$) symmetry and the upper one of p (T$_2$) symmetry, with a relative weight ratio of 1:3. Projected on atomic states, the s-peak then has contributions from H s and B s orbitals, and the p-peak has contributions from H s and B p orbitals. The p-peak can be split due to symmetry breaking caused by the crystal field. This is clearly observed in the lowest two panels of Fig. 5 showing the PDOS on the B$_3$ and H$_3$ atoms with the s peak at $\sim -7$ eV, and a p doublet around $\sim -1$ eV. The splitting between s- and p-peaks is large ($\sim 6$ eV), and the crystal field splitting is much smaller ($\sim 1$ eV).

The interaction between the BH$_4$ units in the crystal lattice leads to a broadening of the peaks due to band formation. The interaction is strongest along the B$_b$(H$_b$)$_2$-Be-B$_b$(H$_b$)$_4$ polymer backbone, see Figs. 4 and 5. This leads to an s-type band in the range $\sim -9$ to $\sim 7.5$ eV, involving contributions from H$_b$, B$_b$, and Be s orbitals, whose DOS has the characteristic shape of a one-dimensional structure, see the upper three panels of Fig. 5. In the range $\sim -5$ to $\sim -2$ eV we find a set of p-type bands. The band widths are smaller than the sp splitting, but they are not negligible, reflecting the covalent bonding along the polymer backbone.

The involvement of the Be atoms can be clarified by calculating the DOS for a Be(BH$_4$)$_2$ structure in which the Be atoms are replaced by a homogeneous background with charge 2+. The result is shown in Fig. 6. The s and p valence bands discussed above disappear and are replaced by much narrower peaks that reflect electron localization on BH$_4^-$ ions in this artificial structure. In other words, the Be atoms in Be(BH$_4$)$_2$ are involved in the covalent bonding. This is in contrast to alkali or alkaline earth boranates and alanates, where the DOS changes little if the cations are replaced by a background charge. The bonding in the latter compounds can be described as an ionic bonding between BH$_4^-$ or AlH$_4^-$ anions and M$^+$ (alkali) or M$^{2+}$ (alkaline earth) cations.
V. REACTION ENTHALPIES

For light elements such as hydrogen, beryllium and boron the quantum character of their atomic vibrations is important. This leads to vibrational energies at zero temperature that are not negligible. For each compound involved in the reaction we calculate its zero point vibrational energy (ZPVE) from the frequencies of the vibrational modes in the optimized structure. For hydrogen molecules also the zero point rotational energy (ZPRE) is not entirely negligible. Reaction enthalpies $\Delta H$ at $T = 0$ K are then calculated from

$$\Delta H = \sum_p (E_{p}^{\text{tot}} + E_p^{\text{ZPVE}}) + E_{\text{ZPRE}} - \sum_r (E_r^{\text{tot}} + E_r^{\text{ZPVE}})$$

(1)

where $E_{p/r}^{\text{tot}}$ denotes the total energy of the reaction products $p$ or reactants $r$, $E_{p/r}^{\text{ZPVE}}$ are the corresponding ZPVEs, and $E_{\text{ZPRE}}$ is the ZPRE of the hydrogen molecules involved in the reaction.

For the hydrogen molecules we calculate a vibrational frequency of 4356 $\text{cm}^{-1}$, in good agreement with the experimental value of 4401 $\text{cm}^{-1}$. The ZPVE, 0.266 eV, is then calculated from the energy levels of a Morse potential,

$$E(n) = \hbar \omega \left( n + \frac{1}{2} \right) - \frac{1}{4D_e} \left[ \hbar \omega \left( n + \frac{1}{2} \right) \right]^2,$$

(2)

where $\omega$ is the vibration eigenfrequency and $D_e$ = 4.57 eV is the dissociation energy. Assuming that ortho- and para-hydrogen are produced in a proportion of three to one, the average ZPVE of a hydrogen molecule is 0.011 eV, using the energy levels given in Ref. [45].

The calculated total energies and ZPVEs of all compounds involved in the reactions are listed in Table III. We consider two possible reaction paths for the formation of Be(BH$_4$)$_2$. In the first path Be(BH$_4$)$_2$ is directly formed from the elements.

$$\text{Be} + 2\text{B} + 4\text{H}_2(g) \rightarrow \text{Be(BH}_4)_2.$$  

(3)

The second path involves the formation of an intermediate compound BeH$_2$.

$$\text{BeH}_2(g) \rightarrow \text{BeH}_2.$$  

(4)

$$\text{BeH}_2 + 2\text{B} + 3\text{H}_2(g) \rightarrow \text{Be(BH}_4)_2.$$  

(5)

The enthalpies of these reaction are calculated using Eq. (1) and the values given in Table III.

Equation (3) gives a reaction enthalpy of $-0.39$ eV/H$_2$ if ZPEs are neglected. If ZPEs are included the reaction enthalpy becomes $-0.12$ eV/H$_2$, which indicated the importance of ZPE corrections for these lightweight compounds. In principle these values are in a range that is useful for hydrogen storage. Using the ionic model of Ref. [46] gives a reaction enthalpy of $-0.02$ eV/H$_2$ (neglecting ZPEs). In the previous section we have already concluded that the bonding in Be(BH$_4$)$_2$ is not purely ionic, i.e. Be$^{2+}$(BH$_4$)$_2^-$. The Be atoms are bonded (partially) covalently to BH$_4^-$, which increases the bonding as compared to the pure ionic picture, resulting in a higher dehydrogenation enthalpy.

Most alanates and other boranates form a simple alkali/alkaline earth hydride when hydrogen is released in a first step. The dehydrogenation of this simple hydride then occurs as a separate second step. Usually the enthalpies are such that only the first step is considered useful for hydrogen storage. For Be(BH$_4$)$_2$ these two steps correspond to the reverse reactions of Eqs. (5) and (4). The calculated reaction enthalpies of Eqs. (4) and (5) are $-0.27$ and $-0.43$ eV/H$_2$ without ZPEs, and $-0.09$ and $-0.13$ eV/H$_2$ with ZPE corrections, respectively.

Not that per H$_2$ Be(BH$_4$)$_2$ is slightly more stable than BeH$_2$. This would indicate that a one-step reaction directly from the elements, Eq. (3), is more favorable than the two-step reaction via the simple hydride, Eqs. (4) and (5). The enthalpy difference however is very small. In addition kinetic barriers may influence the relative importance of the two reaction paths.

We will now focus on finite temperature properties. For the solids we calculate the Gibbs free energy $G(T)$ in the harmonic approximation

$$G(T) = E^{\text{tot}} + H^{\text{vib}}(T) - TS^{\text{vib}}(T)$$

(6)

with

$$H^{\text{vib}}(T) = \int_0^\infty d\omega g(\omega) \left\{ \frac{1}{2} \hbar \omega + \hbar \omega n(\omega) \right\},$$

(7)

and

$$S^{\text{vib}}(T) = k_B \int_0^\infty d\omega g(\omega) \left\{ \beta \hbar \omega n(\omega) - \ln \left[ 1 - e^{-\beta \hbar \omega} \right] \right\},$$

(8)

where $g(\omega)$ is the phonon density of states, $n(\omega) = [\exp(\beta \hbar \omega) - 1]^{-1}$ is the Bose-Einstein occupation number and $\beta = 1/(k_B T)$. The first term in the integral of Eq. (7) gives the ZPVE and the second term gives the finite temperature contribution. Note that we neglect the PV term (i.e. the distinction between energy and enthalpy), which is a good approximation for solids.

For the Gibbs free energy, the enthalpy and the entropy of the hydrogen gas, we use the values given in

| Compound | $E^{\text{tot}}$ | $E^{\text{ZPVE}}$ | $E^{\text{ZPRE}}$ |
|----------|----------------|----------------|----------------|
| Be(BH$_4$)$_2$ | -43.353 | 2.450 | 0.010 |
| BeH$_2$ | -10.797 | 0.542 | 0.004 |
| H$_2$ | -6.803 | 0.266 | 0.011 |
| B | -6.687 | 0.126 | 0.004 |
| Be | -3.729 | 0.091 | 0.004 |

TABLE III: Total energies (with respect to non spin polarized model atoms), zero point vibrational energies (ZPVE) and zero point rotational energy (ZPRE) in eV/formula unit in the relaxed structures.
Fig. 7: (color online) Gibbs free energy of Be\(_{(BH_4)_2}\) and the constituting elements.

Ref. 46. Fig. 7 gives the free energies of Be\(_{(BH_4)_2}\) and the products of the dehydrogenation reaction, i.e. the left and right hand sides of Eq. (3), at the standard pressure of 1 bar. At 162 K the free energy of the products drops below that of the hydride phase. This intersection of the two free energy curves defines the decomposition temperature.

The predicted desorption temperature and equilibrium pressures rely only on the thermodynamics of the reaction. From the fact that experimentally Be\(_{(BH_4)_2}\) seems to be stable at room temperature one may conclude that kinetic barriers play an important role in stabilizing Be\(_{(BH_4)_2}\). In this respect Be\(_{(BH_4)_2}\) is similar to other boranates and alanates, where decomposition temperatures are much higher than what is expected on the basis of thermodynamics and catalysts have to be applied in order to overcome kinetic barriers.

VI. CONCLUSIONS

We use DFT electronic structure calculations at the GGA level to study the crystal structure, electronic structure and thermodynamics of Be\(_{(BH_4)_2}\). We optimize the atomic positions and lattice parameters of all compounds involved in possible formation and dehydrogenation reactions. Both the crystal structure and the electronic structure indicate that the bonding between B and H atoms is covalent, and that the bonding between Be and H atoms is covalent as well as ionic contributions. The crystal structure and the electronic density of states give evidence for \([-BH_4\text{Be}^-]_n\) (helical) polymers.

The enthalpies of possible formation reactions are calculated including zero point energy corrections. The latter are obtained by calculating the phonon frequencies of all compounds involved in the reactions. Since not only hydrogen, but also boron and beryllium are relatively light elements, the zero points energies are relatively large for these compounds. The enthalpy of formation of Be\(_{(BH_4)_2}\) from the elements is \(-0.39 \text{ eV}/\text{H}_2\) without and \(-0.12 \text{ eV}/\text{H}_2\) with zero point energy contributions.

Be\(_{(BH_4)_2}\) differs from other boranates and alanates in that its dehydrogenation to the elements is thermodynamically slightly more favorable than dehydrogenation via the simple hydride BeH\(_2\). In alkali or alkaline earth boranates and alanates dehydrogenation always occurs via the alkali or alkaline earth simple hydride. The different behavior of Be\(_{(BH_4)_2}\) is mainly caused by the high stability of bulk beryllium metal.

Be\(_{(BH_4)_2}\) follows the general trends in the formation energies that have been observed in alkali and alkaline earth alanates and boranates. Boranates are more stable than the corresponding alanates, lighter cations give compounds that are more unstable, and alkaline earth compounds are more unstable than alkali compounds.\(^4\) Indeed Be\(_{(BH_4)_2}\) is less stable than LiBH\(_4\) or Mg(BH\(_4\))\(_2\). We have not found mentioning of beryllium alanate in the literature, which might indicate that this compound would be too unstable.

Using the calculated phonon spectrum we have calculated free energies within the harmonic approximation to assess thermodynamic properties at finite temperature. We obtain a decomposition temperature of 162 K at a 1 bar pressure.
