**ABSTRACT**

The ISO LWS far-infrared spectrum of the ultraluminous galaxy Mrk 231 shows OH and H$_2$O lines in absorption from energy levels up to 300 K above the ground state, and emission in the [O i] 63 μm and [C ii] 158 μm lines. Our analysis shows that OH and H$_2$O are radiatively pumped by the far-infrared continuum emission of the galaxy. The absorptions in the high-excitation lines require high far-infrared radiation densities, allowing us to constrain the properties of the underlying continuum source. The bulk of the far-infrared continuum arises from a warm ($T_{\text{dust}} = 70-100 \text{ K}$), optically thick ($T_{100 \mu\text{m}} = 1-2$) medium of effective diameter 200–400 pc. In our best-fit model of total luminosity $L_{\text{IR}}$, the observed OH and H$_2$O high-lying lines arise from a luminous ($L_{\text{IR}} \sim 0.56$) region with radius $\sim 100 \text{ pc}$. The high surface brightness of this component suggests that its infrared emission is dominated by the AGN. The derived column densities $N(\text{OH}) \gtrsim 10^{17} \text{ cm}^{-2}$ and $N(\text{H}_2\text{O}) \gtrsim 6 \times 10^{16} \text{ cm}^{-2}$ may indicate X-ray dominated region (XDR) chemistry, although significant starburst chemistry cannot be ruled out. The lower-lying OH, [C ii] 158 μm, and [O i] 63 μm lines arise from a more extended ($\sim 350 \text{ pc}$) starburst region. We show that the [C ii] deficit in Mrk 231 is compatible with a high average abundance of C$^+$ because of an extremely overall luminosity to gas mass ratio. Therefore, a [C ii] deficit may indicate a significant contribution to the luminosity by an AGN, and/or by extremely efficient star formation.

1. INTRODUCTION

The peculiar ultraluminous infrared galaxy (ULIRG; $L_{\text{IR}} \gtrsim 10^{12} L_\odot$) Markarian 231 (Mrk 231, 12540+5708) is the most luminous infrared galaxy in the local universe, with a $8-1000 \mu\text{m}$ luminosity of $3.2 \times 10^{12} L_\odot$ (Sanders et al. 2003), and may be a representative example of the link between active galactic nuclei (AGNs) and nuclear starbursts (Scoville 2004). A QSO-like nucleus is evident from many observations: optically it is classified as a Type 1 Seyfert (Boksenberg et al. 1977; Cutri et al. 1984; Baan et al. 1998), it exhibits UV through IR polarization and broad absorption lines (Smith et al. 1995), it has compact X-ray emission (e.g., Gallagher et al. 2002) and extremely compact mid-infrared emission (Soifer et al. 2000), and in the radio it is variable and possesses a parsec-scale jet (Ulvestad et al. 1999; Taylor et al. 1999). Nevertheless, there is also evidence of a compact starburst

in these results as well as in Very Large Array (VLA) observations of H i 21 cm absorption (Carilli et al. 1998), near-infrared observations (Tacconi et al. 2002), and millimeter CO interferometry (Bryant & Scoville 1996; Downes & Solomon 1998, hereafter DS98). Estimates for the starburst luminosity range from 1/3 to 2/3 of the bolometric luminosity (Davies et al. 2004; Lahuis et al. 2007; PIW07). Molecular observations have provided important clues about the concentration and kinematics of the gas in Mrk 231. DS98 showed the presence of an inner nuclear disk of radius $\sim 450 \text{ pc}$ in CO(2−1), and a more extended disk with lower brightness. Most of the molecular gas has been found to be dense ($\sim 10^4 \text{ cm}^{-3}$) and warm ($\sim 70 \text{ K}$) from recent observations of CO and HCN submillimeter lines (Papadopoulos et al. 2007, hereafter PIW07). Lahuis et al. (2007) have inferred embedded starburst chemistry in Mrk 231 and other ULIRGs based on mid-IR Spitzer observations of rovibrational bands of warm/hot HCN and C$_2$H$_2$, while Graciá-Carpio et al. (2006) and Aalto et al. (2007) have inferred XDR chemistry and/or radiative pumping based on anomalous intensity ratios of millimeter lines of HCN, HNC, and HCO$^+$. 

---

303
The bulk of the luminosity in ULIRGs is emitted at far-infrared (FIR) wavelengths, where a number of molecular tracers are detected, mostly in absorption. Prominent lines of OH and H$_2$O were detected using Infrared Space Observatory (ISO) LWS in the FIR spectrum of Arp 220, along with absorption features by radicals such as NH and CH, revealing a chemistry that may be indicative of photodissociation regions (PDs) with plausible contribution by shocks and hot cores (González-Alfonso et al. 2004, hereafter Paper I). However, those species are also expected to be enhanced in XDRs (Meijerink & Spaans 2005), so that the dominant chemistry in the nuclear regions of ULIRGs remains uncertain. In Paper I, the ISO/LWS FIR spectrum of Arp 220 was analyzed by means of radiative transfer calculations, which included a nonlocal treatment of the molecular excitation by absorption of FIR photons. Paper I showed that the population of high-excitation OH and H$_2$O rotational levels, in evidence from absorption in high-lying lines, is pumped through absorption of FIR continuum photons, a process that requires high FIR radiation densities. The detection of these lines thus not only reveals the chemical and excitation conditions in the absorbing regions, it also sheds light on the size and characteristics of the underlying continuum FIR source in spite of the low angular resolution currently available at these wavelengths.

In this paper we extend our approach of Paper I to the ISO/LWS FIR spectrum of Mrk 231, and show that this galaxy spectrum presents striking similarities to that of Arp 220. Specifically, strong absorption in the high-excitation OH and H$_2$O lines is also seen in Mrk 231. Rotationally excited OH in Mrk 231 has been previously detected via the $^2$H$_{1/2}\Lambda$-doublet transitions (Henkel et al. 1987). Very long baseline interferometry (VLBI) observations of the megamaser OH emission at 18 cm wavelength trace an inner torus or disk of size $\sim$100 pc around the AGN (Klöckner et al. 2003), and MERLIN observations were able to map essentially the whole single-dish megamaser OH emission with angular resolution of $\sim$0.3$''$ (Richards et al. 2005). We analyze here both the FIR continuum emission and the high-excitation OH and H$_2$O lines, as well as the [C ii] 158 $\mu$m and [O i] 63 $\mu$m emission lines. In § 2 we present the ISO spectroscopic observations of Mrk 231. In § 3 we first analyze simple models for the FIR continuum emission from Mrk 231, and then examine how well those models reproduce the observed FIR emission and absorption lines. Section 4 summarizes our results. We adopt a distance to Mrk 231 of 170 Mpc ($H_0 = 75$ km s$^{-1}$ Mpc$^{-1}$ and $z = 0.042$).

2. OBSERVATIONS AND RESULTS

The full 43–197 $\mu$m spectrum of Mrk 231 (first shown and discussed by Harvey et al. 1999), was obtained with the LWS spectrometer (Clegg et al. 1996) on board ISO (Kessler et al. 1996). In Figure 1, it is compared with that of Arp 220 (Paper I) rescaled to the same distance (170 Mpc). The grating spectral resolution is $\sim$0.3 $\mu$m in the 43–93 $\mu$m interval (detectors SW1–SW5), and $\sim$0.6 $\mu$m in the 80–197 $\mu$m interval (detectors LW1–LW5), corresponding to $\Delta v \approx 10^7$ km s$^{-1}$. The lines are thus unresolved in velocity space. The $\approx$80$''$ beam size ensures that all the FIR continuum and line emission/absorption from Mrk 231 (CO size $\sim$4$''$; DS98) lies within the ISO LWS aperture.

The data (DTD numbers 5100540, 18001306, and 60300241) were taken from the highly processed data product (HPDP) data set (called uniformly processed LWS01 data), and reduced using version 10.1 of the Off Line Processing (OLP) Pipeline system (Swinyard et al. 1996). We performed subsequent data processing, including co-addition, scaling, and baseline removing, using the ISO Spectral Analysis Package (ISAP; Sturm et al. 1998) and our own routines. In order to obtain a smooth spectrum through-out the whole LWS range, the flux densities given by each detector were corrected by multiplicative scale factors. Corrections were less than 25% except for detectors LW2 and LW3 (100–145 $\mu$m), for which the corrections were 30%. We thus attribute an uncertainty of 30% to the overall continuum level, as well as for the line fluxes.

Figure 1 shows that the FIR spectra of Mrk 231 and Arp 220 are similar in key aspects (see also Fischer et al. 1999), in particular the prominent molecular absorptions mostly due to OH doublets (that will be referred to hereafter as lines) and the lack of strong fine-structure line emission typically seen in less luminous galaxies. A closer inspection of the pattern of line emission/absorption in both sources is shown in Figure 2, where the continuum-normalized spectra are compared. Of particular interest are the clear detections in both sources of the high-excitation OH $\Pi_{3/2}2\rightarrow5/2$ 84 $\mu$m and $\Pi_{3/2}9/2\rightarrow7/2$ 65 $\mu$m lines, with lower level energies of 120 and 290 K, respectively (see § 3). The $3_{20} \rightarrow 2_{21}$ and $3_{31} \rightarrow 2_{20}$ H$_2$O 66–67 $\mu$m lines, both with lower levels at 195 K, are also detected in Mrk 231, as well as the tentatively identified $2_{20} \rightarrow 1_{11}$ line at 101 $\mu$m. It is likely that the increased noise level at $\lambda \approx 160$ $\mu$m is responsible for the non-detection of the high-excitation $\Pi_{1/2}3/2\rightarrow1/2$ OH line in Mrk 231, which is seen in strong emission in Arp 220. While the high-excitation OH and H$_2$O lines at 65–67 $\mu$m are of similar strength in Mrk 231 and Arp 220, the H$_2$O lines at longer wavelengths are undoubtedly weaker in Mrk 231, as seen for the $3_{22} \rightarrow 2_{11}$, $2_{20} \rightarrow 1_{11}$, and $2_{21} \rightarrow 1_{10}$ H$_2$O lines at 90, 102, and 108 $\mu$m, respectively. The weakness of the latter lines in Mrk 231 suggests that the region where the high-lying H$_2$O lines are formed is relatively weak in the FIR continuum at $\lambda = 90–108$ $\mu$m. The Mrk 231 spectrum thus suggests that a warm component with relatively weak contribution to the FIR continuum at $\lambda \approx 80$ $\mu$m is responsible for the observed high-excitation absorptions (§ 3.3). Table 1 lists the line fluxes, continuum flux densities at the corresponding wavelengths, and equivalent widths for the lines detected in Mrk 231.
In the case of Arp 220, we used high spatial resolution continuum measurements available in the literature to infer that Arp 220 is optically thick even in the submillimeter continuum (Paper I; see also Downes & Eckart 2007). The steeper decrease of the flux density with increasing wavelength in Mrk 231, however, suggests that it has lower FIR continuum opacities (Fig. 1). This expectation is further reinforced by the detection in Mrk 231 of the [N ii] 122 μm line, a feature not seen in Arp 220 (Fig. 2). Other notable differences between both sources are that the [O i] 63 μm line is observed in emission in Mrk 231 but in absorption in Arp 220, and that the ground-state 119, 53, and 79 μm OH lines are significantly weaker in Mrk 231 (Fig. 2). In modeling Arp 220, we were forced to invoke an absorbing “halo” to account for these lines; in Mrk 231, no such halo is required (§ 3).

In the spectrum of Mrk 231, the main 119.3 μm OH line appears to be slightly blueshifted relative to the expected position, an effect we attribute to the proximity of the line to the edge of the LW3 detector. There is a nearby weaker redshifted feature at 120 μm which coincides with the expected position of the ground 13/2–11/2 18OH line, and appears as a marginal feature in both the “up” and “down” grating scans. However, the limited signal-to-noise ratio ([1.0 ± 0.4] × 10^{-20} W cm^{-2}), the narrow appearance of the feature (≈0.42 μm), and the fact that it is not blueshifted as the main line, make that assignment only tentative. In Arp 220, the main OH line is not shifted because it does not fall so close to the edge of the detector, as a consequence of the lower redshift of the source. In Arp 220, a redshifted shoulder appears at 120 μm, suggesting the possibility that 18OH may be responsible for it (Paper I). We cannot however be certain that 18OH is detected in any of these sources, but given the high 18OH column densities we derive in some of our models below (§ 3.3) and the fact that values of the 16OH/18OH ratios below the canonical value of 500 may be expected in regions where the interstellar matter (ISM) is highly processed by starbursts (Paper I), our tentative identification should be followed up with future Herschel Space Observatory observations with higher spectral resolution and sensitivity. Finally, the spectrum of Mrk 231 shows a broad feature at the position of the 13/2–11/2 18OH line (53 μm). We note that the blueshifted side of this absorption is coincident with the OH 13/211/2–9/2 line, with a lower level energy of 511 K; however, the proximity of this spectral feature to the edge of the SW2 detector precludes any definitive assignment.

The FIR detections of both NH and NH3 in Arp 220 were reported in Paper I. NH3 was also detected via the 25 GHz inversion transitions by Takano et al. (2005), who derived a NH3 column density 6 times higher than our value. The difference likely arises because of the high FIR continuum opacities in Arp 220, which cause the observed FIR absorptions to trace only a fraction of the total gas column. Since there are no such extinction effects...
at 25 GHz, the NH$_3$ inversion transitions are expected to trace higher NH$_3$ column densities. Figure 2 shows that, by contrast, the NH$_3$ lines are not detected in Mrk 231, although the relatively high noise at 125 μm does not rule out future detection of NH$_3$ with Herschel at a level similar to that of Arp 220.

There are two marginally detected (2.5σ level) spectral features seen at 153.0 and 152.3 μm in the Mrk 231 spectrum (Fig. 3). Although close to the expected position of the main NH feature at 152.2 μm, the 153.0 μm feature appears significantly shifted by 0.25 μm from it, and better coincides with the position of the OH$^+$ 2$_2$–1$_2$ line. Also, the 152.3 μm feature lies at 0.1 μm from it, and better coincides with the position of the OH$^+$ 2$_2$–1$_2$ line. In Paper I, we also suggested that OH$^+$ could contribute to the spectrum of Arp 220 for two reasons: (1) our models were unable to reproduce, using NH and NH$_3$, the observed strong absorption at 102 μm, which coincides with the expected position of the OH$^+$ 3$_4$–2$_3$ line; (2) there was an absorption feature at 76.4 μm that, if real, could be attributed to the OH$^+$ 4$_3$–3$_2$ transition. Since OH$^+$ has never been detected in the Galactic interstellar medium or that of any galaxy, here we only highlight the intriguing possibility of its detection in two ULIRGs. Sensitive, higher-resolution Herschel observations are needed to resolve this tantalizing speculation.

The luminosity of the [C ii] 2P$_{3/2}$–2P$_{1/2}$ fine-structure line at 158 μm is 2.5 times stronger in Mrk 231 than in Arp 220, but given the higher FIR luminosity of this source (Fig. 1), the [C ii] to FIR luminosity ratios are rather similar, with values of 2.5 × 10$^{-4}$ and 2.1 × 10$^{-4}$ for Mrk 231 and Arp 220, respectively (Luhman et al. 2003). These are among the lowest values found in galaxies, illustrating the so-called [C ii] deficit found in ULIRGs. The [C ii] line emission from Mrk 231 is analyzed in § 3.4.

### 3. ANALYSIS

#### 3.1. Models for the FIR Continuum

Figure 4 illustrates several ways that the FIR to millimeter continuum can be fit and interpreted. We first modeled (model A in Fig. 4a) the FIR source in Mrk 231 as an ensemble of identical dust clouds, each of which is heated by its own single central luminosity source. The representative cloud is assumed to be spherical, with radius $R_c$, and is divided into concentric shells whose dust temperatures are computed from the balance of heating and cooling (González-Alfonso & Cernicharo 1999). We used a mixture of silicate and amorphous carbon grains with optical constants from Preibisch et al. (1993) and Draine (1985). The stellar continuum was taken from Leitherer et al. (1999), but results depend only weakly on this choice because the intrinsic continuum is absorbed by the dust and re-emitted at infrared wavelengths. Once the equilibrium temperatures are obtained for each shell, the resulting continuum emission from the cloud is computed and multiplied by $N_c$, the number of clouds in the source required to match the absolute flux densities. This scaled spectrum is shown in Figure 4a. The other three models (B, C, and D, shown in Figs. 4b–4d) use graybodies with uniform dust temperatures $T_d$ to characterize the continuum emission (e.g., Roche & Chandler 1993; Armus et al. 2007).

Assuming that the individual clouds do not overlap along the line of sight, our results do not depend particularly on the radius or luminosity adopted for the model individual cloud because identical results are obtained if $R_d$ is multiplied by a factor of $\alpha_2$, the luminosity by $\alpha_2^{-2}$, and the continuum opacity is kept constant (see Paper I). The models are thus characterized by the luminosity of the whole ensemble, the radial opacity of the clouds at a given wavelength (which we adopt to be 100 μm: $T^{100μm}$), and the equivalent radius of the source, defined as $R_{eq} = N^{1/2} R_c$. These parameters are listed in Table 2.
In model A, the individual clouds are optically thin so that some degree of cloud overlap would yield a similar fit to the continuum while decreasing the value of $R_{\text{eq}}$. For instance, if the clouds are distributed in a spherical volume, $R_{\text{eq}} = N^{1/3} R_c$, giving $R_{\text{eq}} = 400 \text{ pc}$ for clouds with $R_c = 20 \text{ pc}$. However, the predicted opacity through the modeled region, $N^{1/3} \tau_{100\mu m}$, will be much higher than that of an individual cloud, and this physical situation is already described in models B–C, where higher opacities along the line of sight and a more compact region of FIR emission are assumed. In order to avoid this model redundancy, we choose our continuum models such that an individual cloud describes the characteristic continuum opacity ($\tau_{100\mu m}$ in Table 2) and dust temperature through the whole region (disk), so that the resulting extent of the FIR emission is $R_{\text{eq}} = N^{1/2} R_c$.

The observed continuum can be reproduced from model A's cloud ensemble that is optically thin in the FIR. Model A also predicts that the starburst dominates the continuum for $\lambda < 15 \mu m$, while the torus/disk around the AGN would then dominate the mid-infrared continuum, in qualitative agreement with the models by Farrah et al. (2003). The equivalent radius of the starburst is slightly larger than the radius of the outer disk observed by DS98. Because $\tau_{100\mu m}$ is low and $R_{\text{eq}}$ is high, this model predicts that the FIR radiation density is low, a prediction that is not consistent with our models of the observed OH line strengths (§ 3.2).

![Figure 4](image-url)

**Fig. 4.** Different models for the FIR continuum emission from Mrk 231. The whole set of parameters that characterize models A, B, C, and D are listed in Table 2. Flux densities at 800 and 1100 $\mu m$ are taken from Roche & Chandler (1993; corrected for nonthermal emission), at 450 $\mu m$ from Rigopoulou et al. (1996), at 350 $\mu m$ from Yang & Phillips (2007), and at $\lambda < 25 \mu m$ from Rieke (1976).

### Table 2: Models for the Continuum Emission

| Model | Component | $\tau_{100\mu m}$ | $R_{\text{eq}}$ (pc) | $N(\text{H}_2)^a$ (cm$^{-2}$) | $T_d$ (K) | $T_{\text{rad}}$ (K) | $M$ ($M_\odot$) | $L$ ($L_\odot$) | $L/L_{\text{IR}}$ |
|-------|-----------|-------------------|----------------------|-----------------------------|------------|---------------------|----------------|----------------|----------------|
| A...... | ...       | $6.8 \times 10^{-2}$ | 1830                 | $4.6 \times 10^{22}$        | Variable$^b$ | 23                  | $1.0 \times 10^{10}$ | $2.4 \times 10^{12}$ | 0.72          |
| B...... | ...       | 0.55               | 400                  | $3.7 \times 10^{23}$        | 55         | 44                  | $4.0 \times 10^9$   | $1.7 \times 10^{12}$ | 0.50          |
| C...... | ...       | 2.2                | 200                  | $1.5 \times 10^{24}$        | 74         | 71                  | $4.0 \times 10^9$   | $2.0 \times 10^{12}$ | 0.61          |
| D...... | Warm      | 1.1                | 106                  | $7.2 \times 10^{23}$        | 100        | 85                  | $5.5 \times 10^8$   | $1.8 \times 10^{12}$ | 0.56          |
| D...... | Cold      | 0.97               | 350                  | $6.5 \times 10^{23}$        | 47         | 42                  | $5.3 \times 10^9$   | $7.4 \times 10^{11}$ | 0.22          |

$^a$ A gas-to-dust mass ratio of 100 is assumed, together with a mass-absorption coefficient for dust of 44 cm$^2$ g$^{-1}$ at 100 $\mu m$.

$^b$ The temperature is calculated from the balance between heating and cooling; see text for details.
As both $\tau_{100\mu m}$ and $T_d$ are increased in models B and C, the radiation density increases and, therefore, the equivalent size required to reproduce the observed emission becomes smaller. As a consequence, models B and C predict increasing compactness of the dust clouds responsible for the FIR emission, with $R_{eq} = 400$ and 200 pc, respectively. With a single-component model, however, $R_{eq}$ cannot be reduced more than in model C without degrading the quality of the fit. However, a two-component model as shown in model D is able to reproduce the FIR emission, invoking a quite compact ($\sim 100$ pc) and warm ($100$ K) component ($D_{warm}$), and a colder and more extended one that dominates at $\lambda > 80 \mu m$ ($D_{cold}$).

A convenient way to characterize the radiation density in the modeled regions is to compute the radiation temperature at 100 $\mu m$ from

$$T_{rad}(100 \mu m) = \frac{h \nu}{k \ln[1 + (2h\nu^3/\epsilon^2F_{100\mu m})^{1/2}]}$$

where $\Omega = \pi N_i R_i^2/D^2$ is the solid angle subtended by the modeled source, $F_{100\mu m}$ is the predicted flux density at 100 $\mu m$, and other symbols have their usual meanings. $T_{rad}(100 \mu m)$ is also listed in Table 2, together with the gas mass, luminosity, and fraction of the bolometric luminosity for each model. The calculated gas masses assume a gas-to-dust mass ratio of 100. In all cases, they are lower than the dynamical masses determined by DS98 when $R_{eq}$ is identified with the radial extent of the source (and therefore compatible with the inferred rotation velocities in the disk). Our inferred masses are consistent in models B–D with the mass inferred by PIW07, but are in all cases higher, by at least a factor of 2, than the gas masses obtained by DS98. This discrepancy may be explained in at least four possible, different ways: (1) the physical radial extent of the cloud ensemble, which accounts for cloud filling, is given by $R_T = f^{-1/2}R_{eq}$, where $f$ is the area filling factor, so that $R_{eq}$ is a lower limit of $R_T$; (2) our calculated masses depend on the mass-absorption coefficient for dust, which we have assumed to be $k_{100\mu m} = 0.33$ cm$^2$ g$^{-1}$ based on a mixture of silicate and amorphous carbon grains (Preibisch et al. 1993; Draine 1985), but could be up to a factor $\sim 6$ higher if the dust is mainly composed of fluffy aggregates (Kruegel & Siebenmorgen 1994); (3) the gas-to-dust mass ratio may depart significantly from the standard value of 100; and (4) the masses derived by DS98 for Mrk 231 could be lower limits in the light of the submillimeter CO emission reported by PIW07. A combination of these factors may explain our higher values.

The luminosities in Table 2 account for 50%–80% of the observed 8–1000 $\mu m$ infrared luminosity. Model A implicitly assumes that the calculated luminosity has a starburst origin; the luminosity from model B and from the cold component of model D are also attributable to the starburst in view of the spatial extent of the modeled source. Since model C and the warm component of model D are more compact, a combination of AGN and starburst contributions is more plausible. The surface brightness in model C is $4 \times 10^{12}$ $L_\odot$ kpc$^{-2}$, a factor of 2 higher than the peak global value found in starburst galaxies by Meurer et al. (1997), suggesting an important (but uncertain) contribution by the AGN to the observed FIR emission (Soifer et al. 2000). In addition, the luminosity-to-mass ratio of 500 $L_\odot/M_\odot$ coincides with the uppermost limit proposed by Scoville (2004) for a starburst. The very high surface brightness ($1.3 \times 10^{13}$ $L_\odot$ kpc$^{-2}$) and luminosity-to-mass ratio ($\sim 3300$ $L_\odot/M_\odot$) of the warm component of model D ($D_{warm}$), as well as its compactness, persuasively indicate that this component is most probably dominated by the AGN. The most plausible relative contributions by the AGN and the starburst to $D_{warm}$ are discussed in § 4.

In summary, different approaches can be used to successfully fit the observed FIR continuum emission, with the properties of the clouds that emit that radiation in these approaches spanning a wide range of possible physical scenarios. But ISO LWS has provided us with spectroscopic information, and we show next how the observed high excitation OH and H$_2$O lines impose important constraints on these continuum models.

### 3.2. Equivalent Widths

We analyze the OH equivalent widths assuming that the OH molecules form a screen in front of the IR source. The strengths of the $\Pi_{3/2, J=7/2-5/2}$ and $9/2-7/2$ OH doublets at 84 and 65 $\mu m$ enable us to conclude that the excited OH covers a substantial fraction of the FIR emission region. Assuming that each line of the 84 $\mu m$ doublet absorbs all the background 84 $\mu m$ continuum over a velocity range of 250 km s$^{-1}$ along each line of sight, and that there is no significant re-emission in the line, the covering factor is $\sim 50\%$. This value may be considered a lower limit for the following reasons. The submillimeter CO line profiles shown by PIW07 have FWHMs of 200–250 km s$^{-1}$, and the lines are expected to be broadened by velocity gradients and, in particular, by the disk rotation; therefore, the velocity range of 250 km s$^{-1}$ assumed above is probably an upper limit. DS98 inferred local turbulent velocities of up to 60 km s$^{-1}$ at inner radii (100 pc) and decreasing as $r^{-0.3}$. If we adopt an intrinsic Gaussian line profile with the highest value of the turbulent velocity, $\Delta V = 60$ km s$^{-1}$, and saturate the 84 $\mu m$ line to the degree that an effective width$^2$ of 250 km s$^{-1}$ is obtained for each component of the doublet, the derived 84 $\mu m$ foreground opacity at line center is $\sim 50$, but the high column density required for this opacity is hard to reconcile with that inferred from the other observed OH line strengths (§ 3.3). Finally, some significant re-emission in the 84 $\mu m$ OH line is expected because the $\Pi_{3/2, J=9/2-7/2}$ OH line at 65 $\mu m$ that originates from its upper level is detected in absorption. We therefore conclude that the observed 84 $\mu m$ OH absorption is widespread, and probably covers the bulk of the 84 $\mu m$ continuum emission regions. On the other hand, the opacities in the high lying 65 $\mu m$ line should only be moderate; for reference, if we adopt for each component an upper limit of 150 km s$^{-1}$ on the effective velocity interval for the absorption at each sight line, the minimum covering factor for this line is then 25%. It is therefore possible that the OH responsible for the 65 $\mu m$ absorption does not entirely coincide with that producing the 84 $\mu m$ absorption but is only a fraction of the latter, consistent with its lower energy level being at nearly 300 K. Nevertheless, for the sake of simplicity, we assume in this section that both lines arise in the same region—one that, on the basis of the 84 $\mu m$ OH strength, covers the total FIR continuum. The derived OH column densities will be lower limits, and the inferred properties of the continuum source will be associated with at least $\sim 50\%$ of the observed FIR emission.

The equivalent widths $W$ are then given by

$$W = 2 \left[1 - \frac{B_\nu(T_{ex})\Omega}{F_j}\right] \int (1 - \exp(-\tau_v))dv,$$

where $B_\nu(T_{ex})$ is the blackbody emission at the excitation temperature $T_{ex}$ of the line, $\Omega = \pi R_{eq}^2/D^2$ is the solid angle subtended by the source, $F_j$ is the observed continuum flux density at the

$^2$ The effective width is defined here as $\int (1 - \exp(-\tau_v))dv$, where $\tau_v = \tau_0 \exp(-v/\Delta V)^2$ and $\tau_0$ is the line opacity at line center.
wavelength \( \lambda \) of the line, \( \tau_v \) is the line opacity at velocity \( v \), and the factor 2 accounts for the two lines that compose a doublet. The values of \( W \) are positive for absorption lines, and negative for lines observed in emission. Equation (2) applies both to optically thin and optically thick lines. For optically thin lines, \( W \) is proportional to the assumed column density; for very optically thick lines, \( W \) becomes insensitive to the column density and scales linearly with the turbulent velocity. Based on DS98, we have adopted \( \Delta V = 40 \text{ km s}^{-1} \), which is probably accurate within 50%.

The fractional level populations and column densities (and hence the opacities), and blackbody temperatures required to obtain \( W \) from equation (2) can be estimated from a given column density \( N(\text{OH}) \), and by assuming that the excitation temperature \( T_{\text{ex}} \) is the same for all OH transitions. This assumption is certainly only an approximation. The OH levels are pumped primarily through absorption of FIR photons; this is quite a general model result when both the ground and the excited OH rotational lines (except the 163 \( \mu \text{m} \) one) are observed in absorption (see the similar conclusion in Paper I for the case of Arp 220, as well as the case of the \( \text{H}_2\text{O} \) lines at 25–45 \( \mu\text{m} \) in Orion/IRc2; Wright et al. 2000). When radiative excitation dominates, the level populations tend toward equilibrium with the radiation field within the inner cloud, and the excitation temperatures are similar for all transitions in those regions. However, the observed absorptions are produced close to the cloud boundary where the OH molecules are illuminated from only one side and \( T_{\text{ex}} \) is less than the radiation temperature. Due to trapping effects, the lines with the highest opacity (119 and 84 \( \mu\text{m} \) OH lines) remain more excited than the other lines at inner locations of the region, but their \( T_{\text{ex}} \) values decrease more steeply outwards and fall below the \( T_{\text{ex}} \) values of other, thinner lines close to the cloud boundary. The detailed, non-local radiative transfer models described in \( \S \) 3.3 show that the assumption of equal \( T_{\text{ex}} \) is only approximately valid for the 119 and 84 \( \mu\text{m} \) lines, but for the other lines, and in particular for the 65 and 53 \( \mu\text{m} \) lines, \( T_{\text{ex}} \) may be higher or lower depending on position in the region. Nevertheless, the opacities of the 119, 84, 65, and 53 \( \mu\text{m} \) lines are mostly determined by the \( T_{\text{ex}} \) of the 119 and 84 \( \mu\text{m} \) lines. As a result, the following analysis of the radiation density (or, equivalently, \( R_{\text{eq}} \), required to account for the observed absorptions) is accurate, at least to a first approximation.

The three parameters now required to estimate \( W \) from equation (2) are then \( N(\text{OH}) \), \( R_{\text{eq}} \), and \( T_{\text{ex}} \). Figure 5 shows the expected values of \( W \) for models A, B, and C as a function of \( T_{\text{ex}} \). The observed absorptions of the 119, 84, and 53 \( \mu\text{m} \) lines, and compares them with the observed values. Each panel assumes a value of \( R_{\text{eq}} \) that corresponds to the continuum models A, B, and C described in \( \S \) 3.1 (see also Table 2). The values of \( N(\text{OH}) \) used for each model are just reference values discussed below.

The spectral line analysis of Model A (Fig. 5a) shows that this scenario can be ruled out as the main source of FIR radiation from Mrk 231 (Fig. 4a); the continuum model predicts low \( T_{\text{rad}} \) (between 20 and 34 K for the different lines) but the observed absorption in the 65 \( \mu\text{m} \) line, with lower level energy of 290 K, requires a much higher \( T_{\text{ex}} \). Furthermore, the 119 and 84 \( \mu\text{m} \) lines are expected to be in emission (\( W < 0 \)) as soon as \( T_{\text{ex}} \) becomes higher than 20 and 25 K (which, on the other hand, is not possible for radiative excitation). With such a low value of \( T_{\text{ex}} \), \( W_{65 \mu\text{m}} \) is negligible even with our adopted screen \( N(\text{OH}) = 10^{18} \text{ cm}^{-2} \), a value that overestimates \( W_{53 \mu\text{m}} \) by more than a factor of 2.

The above problems still remain to some extent in model B, when \( R_{\text{eq}} \) is reduced to 400 pc (Fig. 5b). Here the dust radiation temperatures allow the lines to be seen in absorption up to \( T_{\text{ex}} \approx 40 \text{ K} \); however, \( W_{65 \mu\text{m}} \) is underestimated by more than a factor of 2 for the adopted \( N(\text{OH}) = 3 \times 10^{17} \text{ cm}^{-2} \), yet this column density still overestimates the absorption of the 53 \( \mu\text{m} \) line. Although model B cannot account for the 65 \( \mu\text{m} \) line strength, a region of similar size but lower \( N(\text{OH}) \) could contribute to the observed absorptions of the 119, 84, and 53 \( \mu\text{m} \) lines.

The single-component model that best accounts for the four observed OH lines is model C, with \( R_{\text{eq}} = 200 \text{ pc} \) (Fig. 5c). The corresponding continuum model (Fig. 4c), with \( T_d = 74 \text{ K} \), also fits the overall FIR continuum emission rather well. Significantly, our models in \( \S \) 3.3 show that the excitation temperatures required to reproduce the observed equivalent widths, 40–60 K, are those computed at the cloud surface if the OH is excited by the infrared emission from a blackbody at \( T_d = 74 \text{ K} \). Finally, the dust...
temperature and gas mass (Table 2) in model C are consistent with the gas temperature and H$_2$ mass derived by PIW07 from the submillimeter CO and HCN emission. They found that this warm gas component hosts most of the molecular mass in the Galaxy. The H$_2$ column density, $N$(H$_2$)/C$^{12}$ = 5.10$^{24}$ cm$^{-2}$, indicates high optical depths, as in the Galactic Sgr B2 molecular cloud, but Mrk 231 is much warmer. If the column density in Mrk 231 is concentrated in a face-on disk of thickness $H$ = 23 pc, as concluded by DS98, the expected density is $n$(H$_2$) $\sim$ 2 × 10$^4$ cm$^{-3}$, just the amount needed to account for the CO submillimeter lines (PIW07). On the other hand, if this warm and dense component is identified with the inner disk of radius 460 pc reported by DS98, the area filling factor is $f$ $\sim$ 0.2. In spite of the general agreement between our model C with other observations, a closer inspection of this model ($\S$ 3.3) reveals some discrepancies with other OH and H$_2$O lines that suggest that a slightly modified scenario can better explain the overall observed absorption patterns.

### 3.3. Models for OH and H$_2$O

Radiative transfer modeling of the observed OH and H$_2$O lines was done using the code described in González-Alfonso & Cernicharo (1997, 1999), which computes the statistical equilibrium populations of a given molecule in spherical symmetry. Line broadening is assumed to be caused by microturbulence. Our code accounts for a nonlocal treatment of the radiative trapping in the molecular lines and of the excitation through absorption of photons emitted by dust, as well as for collisional excitation. Both line and continuum opacities for photons emitted in both lines and continuum are taken into account. Collisional rates were taken from Offer et al. (1994) and Green et al. (1993) for OH and H$_2$O, respectively. As we also found for Arp 220 (Paper I), the overall excitation is dominated by absorption of FIR continuum photons in all models. If shock conditions (high density and temperature) were assumed, only the absorption in the lowest-lying lines would be significantly affected. Once the continuum model is fixed, our results only depend on the molecular column densities and turbulent velocity (see Paper I for a fuller description).

As mentioned above (§ 3.2), the observed absorption strengths are not sensitive to the amounts of OH and H$_2$O in the inner regions of the modeled regions, but only to the amounts of OH and H$_2$O that are close to the cloud (or disk) boundary. For this reason, we calculate two values for the derived molecular column densities: $N^\text{scr}(X)$ denotes the column density for a shell of species X covering the infrared source (i.e., the screen case), whereas $N^\text{mix}(X)$ is the inferred column density for models where X and dust are evenly mixed (the mixed case). Evidently $N^\text{mix}$ will be much higher than $N^\text{scr}$, but from our data there are only a few, nondefinitive ways to discriminate between the alternatives. The 163 $\mu$m OH and 120 $\mu$m $^{18}$OH lines are stronger in the mixed case, but neither of these features is unambiguously detected.
and a 0 to C+ abundance ratio of 2.1.

Nevertheless, we do not find any strong arguments for thinking that OH and H2O are only present on the surface of the disk, and that OH and H2O are only present on the surface of the disk, and in particular if the version with OH and dust coexistent (the mixed case), which predicts high OH column densities (Table 3), is compatible with the low [C ii] to FIR flux ratio seen and previously reported in Mrk 231 (Luhman et al. 2003). In Paper I we assumed a C+ to OH abundance ratio of 100 (based on standard gas-phase carbon abundance, and the abundance of OH found in the galactic center and Sgr B2), and found a remarkable agreement between the predicted and observed [C ii] line flux in Arp 220. In the present case we have searched for the required C+ and O6 column densities in models C and D (mixed case) that fit the observed [C ii] and [O i] line fluxes, with the additional constraint that the [O i] 145 μm line is not detected to a limit of 4 × 10⁻²¹ W cm⁻² (see also Luhman et al. 2003). In model D, the C+ abundance was assumed to be the same in both components. Both the [C ii] and [O i] lines are expected to form within a velocity range as a consequence of the relatively high column densities of [C ii] and [O i] lines, but as long as T_k is sufficiently high than the energy of the upper level, ≈90 K. In the regions directly exposed to the far-UV radiation field, all of the carbon and oxygen are expected to be in their ionized and atomic forms, respectively. Therefore an O6 to C+ abundance ratio of 2.1, corresponding to O5 and C+ gas-phase abundances of 3 × 10⁻⁴ and 1.4 × 10⁻⁴ (Sembach & Savage 1996), is imposed. Using the collisional rates by Launay & Roueff (1977a, 1977b) for carbon and oxygen, we then searched for the density n(H) and column densities Nmix(C+) and Nmix(O6) required to match the line strengths. The results for both models C and D are also in Figure 6, and the calculated column densities are listed in Table 3.

We could not find any satisfactory fit to the three atomic lines with model C. Since the continuum is optically thick at λ < 150 μm, extinction effects are important in the [O i] 63 μm line, and densities higher than 5 × 10⁻⁴ cm⁻³ were required to account for it. On the other hand, high column densities were also needed to fit the [C ii] line, and the final result is that all combinations that fitted both the [C ii] and the [O i] 63 μm lines yielded more flux than the upper limit for the undetected [O i] 145 μm line. The model in Figure 6 shows the result for n(H) = 8 × 10⁻³ cm⁻³ and T_k = 400 K. Only high densities (∼10⁵ cm⁻³) and relatively low temperatures (≤150 K) can approximately match both O6 lines, but then the [C ii] line is underestimated by more than a factor of 2.

In contrast, model D allowed us to find a more satisfactory fit to the three lines. As we argue below, the compact-weak component is expected to give negligible emission in the C+ and O6 lines. The extended component Dcold, with its moderate dust temperature (T_d = 47 K) and continuum opacity, can explain the [O i] 63 μm line with a density and column density lower than in model C, thereby predicting a weak 145 μm line. The model in

### Table 3

| Model | C   | D (Warm) | D (Cold) |
|-------|-----|----------|----------|
| N(H2)(cm⁻³) | 1.5 × 10²⁴ | 7.2 × 10²³ | 6.5 × 10²³ |
| ΔV (km s⁻¹) | 40 | 40 | 40 |
| N³(OH)(cm⁻³) | 1.0 × 10¹⁷ | 9.2 × 10¹⁶ | 6.1 × 10¹⁶ |
| N³( OH)(cm⁻³) | 4.5 × 10¹⁸ | 1.4 × 10¹⁸ | 9.7 × 10¹⁷ |
| N³(H²O)(cm⁻³) | 5.4 × 10¹⁸ | 6.1 × 10¹⁶ | ≈5 × 10¹⁵ |
| N³(H²O)(cm⁻³) | 2.0 × 10¹⁸ | 9.6 × 10¹⁷ | ≈1 × 10¹⁷ |
| N³(C+)(cm⁻³) | 1.3 × 10⁻⁶ | 1.3 × 10⁻⁶ | 1.5 × 10⁻⁷ |
| N³( O+)(cm⁻³) | 2.3 × 10²⁰ | 3.1 × 10⁹e | 2.8 × 10⁹e |
| N³( O+)(cm⁻³) | 4.9 × 10²⁰ | 6.7 × 10⁹e | 6.0 × 10⁹e |

a Models correspond to the continuum models listed in Table 2 and shown in Figs. 4c and 4d.

b N³(X) is the column density of a shell of species X surrounding the continuum source, and N³(X) is the column density for the case that species X is evenly mixed with the dust.

c Abundances are given relative to H₂ using the N³(X) values.

d The column densities of C+ and O are computed by assuming gas at 400 K, and a O6 to C+ abundance ratio of 2.1.

e Equal averaged abundances are assumed in the warm and cold components of model D.
Figure 6 uses $n(\text{H}) = 5 \times 10^3 \text{ cm}^{-3}$ and $T_K = 400 \text{ K}$ for $D_{\text{cold}}$. It is remarkable that when we generated the same model but excluded the effect of dust, we found that the [O i] $63 \mu$m line was stronger by a factor of 4.2. The dust has a small effect on the other two [O i] $145 \mu$m and [C i] $158 \mu$m lines, but can substantially lower the [O i] $63 \mu$m line because the absorption of $63 \mu$m line-emitted photons by dust grains (i.e., extinction) is more important than the additional pumping of $O^0$ atoms by $63 \mu$m dust-emitted photons. Therefore, the ratio of the [C i] $158 \mu$m line to the [O i] $63 \mu$m line, observed of order unity, is reproduced with higher densities and temperatures than in previous studies: Figure 4 of Kaufman et al. (1999) shows that $I([\text{O i}] 63 \mu\text{m})/I([\text{C i}] 158 \mu\text{m}) \approx 1$ for $n(\text{H}) = 5 \times 10^3 \text{ cm}^{-3}$ and $G_0 \approx 10^2$, corresponding to a temperature somewhat higher than 100 K (Fig. 1 of Kaufman et al. 1999). Including dust leads to a similar intensity ratio for $T_K = 400 \text{ K}$, or $G_0 \gtrsim 10^2$. On the other hand, our model for $D_{\text{cold}}$ yields $I([\text{C i}] 158 \mu\text{m})/I([\text{O i}] 145 \mu\text{m}) \approx 7.5$, which implies $G_0 \approx 10^3$ for the above density (see Fig. 6 of Luhman et al. 2003). These results suggest that the effect of extinction cannot be neglected when modeling the [O i] $63 \mu$m line in sources that are optically thick at wavelengths shorter than $100 \mu$m. Self-absorption by foreground low-excitation clouds may also lower the flux of the [O i] $63 \mu$m line and to a lesser extent that of the [C i] line (Fischer et al. 1999; Vastel et al. 2002; Luhman et al. 2003; Paper I).

To compare our results for line intensity ratios involving the [O i] $63 \mu$m line with the corresponding plots shown by Luhman et al. (2003), one should use the versions of our models that ignore dust, because the intensities given in the models by Kaufman et al. (1999) are uncorrected for extinction. In our models that ignore dust, [C ii]/[O i] $\sim 0.4$ and ([C ii] + [O i])/[IR] $\sim 2 \times 10^{-3}$. Here, the FIR flux corresponds to that of component $D_{\text{cold}}$ (Table 2). Using these values in Figure 4 of Luhman et al. (2003), one obtains $n(\text{H}) = a \times 10^3 \text{ cm}^{-3}$ and $G_0 = b \times 10^3$, roughly consistent with our input model parameters.

The C$^+$ and O$^0$ column densities required to fit the lines in model $D_{\text{cold}}$ are rather high. The averaged C$^+$ and O$^0$ abundances are $2.2 \times 10^{-5}$ and $4.6 \times 10^{-5}$ relative to H nuclei, respectively. If the C$^+$ to OH abundance ratio is 100 (Paper I), the mixed column density of OH is overestimated by a factor of 3. In any case, the $N_{\text{mix}}$($C^+$) values indicate that an important fraction of C nuclei is in ionized form, $\gtrsim 15\%$ in model $D_{\text{cold}}$ for a gas phase carbon abundance of $1.4 \times 10^{-4}$ (Sembach & Savage 1996). The corresponding mass of atomic gas is $8 \times 10^8 M_\odot$, at least 0.1 order of magnitude higher than the amount estimated in M82 and NGC 278 (Wolfire et al. 1990; Kaufman et al. 1999). As mentioned above, C$^+$ is expected to be abundant only in regions within $A_P \lesssim 2$ mag from the surfaces of PDRs, and the relatively high fraction of C$^+$ derived above indicates that those regions must be widespread in the Mrk 231 disk. On the other hand, one possible interpretation of the high H$_2$ column densities required to generate the radiation field needed to account for the OH lines is that we are viewing a number of PDRs that overlap along the line of sight (see also Section 4).

We now check the possibility that a significant fraction of the [C ii] $158 \mu$m emission arises from a more extended region, such as the outer disk found by DS98 in CO. For an outer disk mass of $2 \times 10^8 M_\odot$ and density of $10^2 \text{ cm}^{-3}$ (DS98), and using an upper limit for the C$^+$ abundance of $\lesssim 10^{-4}$ and collisional rates at 250 K (from Launay & Roueff 1977a), we calculate that $\lesssim 1/4$ of the observed [C ii] line arises from this extended region. Therefore we do not expect much contribution from it, unless the C$^+$ is concentrated in clumps of much higher density.

Our model results can be used to re-examine the issue of the [C ii] line deficit found in ULIRGs. Contrary to what might be expected from the low [C ii] to FIR luminosity ratio in Mrk 231, relatively high average abundances of C$^+$ are required in $D_{\text{cold}}$ to reproduce the [C ii] line. Explanations based on self-absorption effects, extinction by dust, effects of dust-bounded H II regions, high $G_0/n$, and high formation rate of CO at the expense of C$^+$ have been invoked to account for the [C ii] deficit (Luhman et al. 1998, 2003; Malhotra et al. 2001; PIW07; Paper I, and references therein). In our models for Mrk 231, the high abundance of C$^+$ yields the observed low [C ii] to FIR luminosity ratio because of the high luminosity-to-gas mass ratio ($L/\dot{M}$) of our continuum models. In both model C and model D, an overall $L/\dot{M} \approx 500 L_\odot/\dot{M}_\odot$ is derived (Table 2), where the gas mass includes both the atomic and molecular components. We argue that, if this extreme $L/\dot{M}$ ratio applies to the whole region from which the FIR emission arises, as appears to be the case for Mrk 231, the [C ii] line strength relative to the infrared emission can never attain values in excess of 0.1%. The [C ii] luminosity emitted per unit of total gas mass is given by

$$
\phi_{\text{[C ii]}} = \frac{1}{1 + (g_1/g_2) \exp \left[ E_u/kT_{\text{ex}} \right]} n_{\text{C}^+} A_{\text{ul} h \nu},
$$

where $g_1$ and $g_2$ are the degeneracies of the lower and upper level, $E_u$ is the upper level energy, $A_{\text{ul}}$ is the Einstein coefficient for spontaneous emission, and $n_{\text{C}^+}$ denotes the number of C$^+$ ions per unit of total gas mass (including all components). It is assumed in equation (3) that the line is optically thin. In the limit $T_{\text{ex}} \gg E_u/k$ one obtains

$$
\phi_{\text{[C ii]}} \approx 0.5 \chi(C^+) \frac{L_{\odot}}{10^{-4} M_\odot},
$$

where $\chi(C^+)$ denotes the average C$^+$ abundance relative to total H nuclei. Therefore, the expected [C ii]-to-IR emission is

$$
\frac{\phi_{\text{[C ii]}}}{L/\dot{M}} \approx 10^{-3} \frac{\chi(C^+)}{10^{-4}} \frac{L_\odot}{M_\odot},
$$

for $L/\dot{M} = 500 L_\odot/\dot{M}_\odot$. Hence, even assuming the highest nearly possible $\chi(C^+) \sim 10^{-4}$, the [C ii]-to-IR ratio is not expected to be above $10^{-3}$ for such high values of $L/\dot{M}$. The reason is simply the limited reservoir of gas, and hence of C$^+$ ions, per unit of output power. High $L/\dot{M}$ values are in Mrk 231 primarily due to the contribution of the AGN, but could also be associated with high star formation efficiencies (maybe extreme; see Scoville 2004): if we attribute the total infrared luminosity to FUV heated grains in PDRs and use the units of $G_0$ (i.e., the Habing Field of $1.6 \times 10^{-3}$ ergs cm$^{-2}$ s$^{-1}$) to calculate the $L/\dot{M}$ for a PDR column density of $A_P = 10$ mag with the standard gas-to-extinction conversion $N(H + 2H_2)/A_P \sim 2.5 \times 10^{21}$ cm$^{-2}$ mag$^{-1}$ (e.g., Dickman 1978), we find that the value of $G_0$ that corresponds to $L/\dot{M} = 500 L_\odot/\dot{M}_\odot$ is $2.5 \times 10^4$, which we express for the general case as

$$
L/\dot{M} = 500 \left( \frac{G_0}{2.5 \times 10^4} \right) \left( \frac{10 \text{ mag}}{A_P} \right) \frac{L_\odot}{M_\odot},
$$

For simplicity, the luminosity accounts here for the total infrared emission as derived in our models, whereas in previous studies the FIR emission was defined between 40 and 120 $\mu$m, the correction factor is less than 2 (see Sanders & Mirabel 1996).
so that high L/M values would indicate high G_0 values. For PDRs with G= 2.5 x 10^4 and A_e ~ 10 mag, the average C⁺ abundance is ~2 x 10^{-3} (i.e., carbon is ionized within ~2 mag of the surfaces of PDRs) and \phi_{\text{\textit{CO}}}/(L/M) will attain the lowest values observed in ULIRGs.

In our favored model D, the component D_warm (L/M = 3270 L☉/M☉), which emits most of the IR luminosity, could only account for the [C ii] line if essentially all gas-phase carbon were in ionized form. However, this seems implausible, as the C⁺ abundance in XDRs is \chi(C^+⁻) ~ a few x 10^{-3} (Meijerink & Spaans 2005), and FUV photons from stars are absorbed in thin shells of dust on the surfaces of PDRs. With the assumed column densities in Table 3, the calculated contribution from D_warm to the observed [\text{C ii}] emission is only 8%, the [O i] 145 \mu m flux is 15% of the upper limit, and the [O i] 63 \mu m is predicted in weak absorption against the continuum. (In this calculation, T_k = 10^3 K and n = 2 x 10^3 cm⁻³ are assumed, so that the atomic region is in pressure equilibrium with the cooler molecular gas with T_k = 10^2 K and n = 2 x 10^4 cm⁻³.) It is therefore expected that the strongest source of infrared radiation (the warm component) gives low [C ii] and [O i] line emission even if one assumes relatively high averaged fractional abundances for C⁺ and O. As in Luhman et al. (2003), we then invoke a component that emits strongly in the FIR but yields weak emission in the [C ii] and [O i] lines. In contrast to Luhman et al. (2003) however, we leave open the possibility that D_warm has a relatively high C⁺ abundance, as expected from both XDR and PDR chemistry. In starburst and normal galaxies, the moderate star formation efficiencies (e.g., ~15 L☉/M☉ in NGC 1068; Planesas et al. 1991), implying lower values of G_0, will not place such a strong limit on the C⁺ cooling rate relative to the infrared emission. We suggest, then, that the [C ii] 158 \mu m line deficit found in ULIRGs may be associated with a high L/M ratio that, allowing a relatively high C⁺ abundance, indicates an important contribution to the FIR emission by an AGN, and/or a high star formation efficiency.

4. DISCUSSION AND CONCLUSIONS

Simultaneous modeling of the FIR continuum and line absorptions is the only consistent way to derive from FIR observations the physical and chemical properties of bright infrared galaxies, where due to high radiation densities, the OH and H2O lines are pumped through absorption of continuum photons. In Mrk 231, the high-lying 65-68 \mu m OH and H2O lines are indicated the presence of a compact (~100 pc) and warm (~100 K) region, presumably located around the AGN, with high continuum opacity (\tau_{100\mu m} ~ 1). The size of this region is comparable to (although somewhat larger than the inner nuclear disk where the OH megamasers have been observed from VLBI observations (Klöckner et al. 2003), and is similar to the spatial extent of the regions where the bulk of the OH megamaser emission is generated (regions C, NE, and SW in Fig. 5 of Richards et al. 2005). This strongly suggests that we are observing the FIR counterpart of the 18 cm OH emission (e.g., Skinner et al. 1997). Richards et al. (2005) estimate N(OH) ~ 1.5 x 10^{15} cm⁻² in 1 pc clouds where \Delta V ~ 1.7 km s⁻¹; therefore, N(OH)/\Delta V ~ 10^{15} cm⁻² (km s⁻¹)⁻¹. In both the warm and cold components of model D, we have obtained N^{\text{vert}}(OH)/\Delta V ~ 1.5 x 10^{15} cm⁻² (km s⁻¹)⁻¹, in rough agreement with the estimates by Richards et al. (2005). The “screen” case is most appropriate for comparison here because the OH megamasers amplify the background radio continuum emission.

The nuclear region is surrounded by a more extended (R_{\text{ref}} ~ 350 pc) and colder (~45 K) region, which produces the bulk of the [C ii] and [O i] line emissions and contributes to the low-lying OH lines. Allowing for an area filling factor of 0.6-0.7, the total extent of the FIR emission is then comparable to the size of the CO (inner) disk (Bryant & Scoville 1996; DS98). The inferred densities [n(H_2) ~ 10^4 cm⁻³] may explain the submillimeter CO emission detected by PIM07 and somewhat lower densities (a few x 10^3 cm⁻³) can account for the [O i] line emission. We do not however rule out the possibility that some of the FIR emission arises from a more extended region, such as the outermost disk observed by DS98 in the millimeter CO lines or the much more extended region observed in soft X-rays (Gallagher et al. 2002).

The FIR emission from D_warm is probably dominated by the AGN, as pointed out in § 3.1. Davies et al. (2004) estimated that, within a radius of 330 pc, the starburst luminosity accounts for (0.8-1.3) x 10^{12} L☉; since the luminosity for the component D_cold is ~7.5 x 10^{11} L☉, the starburst luminosity contribution from D_warm is most probably <6 x 10^{11} L☉. Davies et al. (2004) also estimated that, within 100 pc of the AGN (the size of D_warm), the starburst contribution is ~3.2-4.7 x 10^{11} L☉, in agreement with the aforementioned upper limit. On the other hand, the extended (360 x 260 pc²) radio continuum 1.4 GHz emission detected by Carilli et al. (1998) is compatible with both the whole FIR emission arising from the starburst (yielding an IR-to-radio flux density ratio of Q = 2.5; Carilli et al., 1998), and only the D_cold FIR emission arising the starburst (yielding Q = 2.1). If one now assumes that the starburst contribution to the FIR emission of D_warm is 3 x 10^{11} L☉, the resulting Q = 2.3 (in agreement with the median value of Q = 2.3 ± 0.2 in normal galaxies; Condon 1992, and references therein). In addition, the surface brightness and luminosity-to-mass ratio of D_warm, due to only the starburst component would then be 2 x 10^{12} L☉ kpc⁻² and 550 L☉/M☉, which are probably upper limits for a starburst. In summary, our preferred model D favors that ~2/3 of the bolometric luminosity from Mrk 231 is due to the AGN.

Although the chemistry of the extended starburst D_cold component, where the lower-lying OH lines and the bulk of the [C ii] 158 \mu m and [O i] 63 \mu m lines are generated, appears to be dominated by PDRs, the dominant chemistry of the warm component may be of a different nature. Since the compactness of D_warm suggests that its FIR emission is dominated by the AGN, and given the high X-ray intrinsic luminosity of the AGN (~10^{44} erg s⁻¹) in the 2–10 keV band (Braito et al. 2004), we consider the possibility that the derived OH and H2O column densities can be better explained in terms of XDR chemistry. Calculations by Meijerink & Spaans (2005) show that, in dense XDRs with N_{H_2} ~ 10^{24} cm⁻², the OH and H2O column densities are expected to attain values of ~10^{18} cm⁻², similar to the values that we have derived in the mixed case. Furthermore, the Compton-thick screen with N_{H_2} ~ 2 x 10^{24} cm⁻² required to block the primary X-ray emission (Braito et al. 2004) could be partially identified with D_warm, with similar column density. Therefore an XDR may naturally explain the observations of high-lying OH and H2O lines in Mrk 231. Nevertheless, both OH and H2O are also tracers of starburst chemistry, and a number of PDRs and hot cores overlapping along the line of sight could in principle yield the column densities required to explain our observations at least in the screen case, and could then mimic an XDR. We conclude that further observations are still required to discern between XDR and starburst chemistry.

We suggest that the [C ii] 158 \mu m line deficit in Mrk 231, and also probably in Arp 220 (see Paper I), is primarily due to a component that dominates the FIR emission but emits weakly in the [C ii] line, as previously suggested by Luhman et al. (2003). However, we also suggest that this component may still be rich in
C\(^{+}\), but with an extreme luminosity-to-gas mass ratio that limits the [C\(\text{ii}\)] luminosity per unit of luminous power in the continuum. Our derived luminosity to H\(_{2}\) mass ratio of 500 \(L_{\odot}/M_{\odot}\) is high; future studies will indicate whether it can be applied to other ULIRGs with similar [C\(\text{ii}\)] deficits.

Given the high C\(^{+}\) column densities (a few \(\times 10^{19}\) cm\(^{-2}\)) required to account for the [C\(\text{ii}\)] 158 \(\mu\)m line emission, the H\(_{2}\) columns derived toward the extended component are unlikely to be associated with non-overlapping star-forming regions surrounded by optically thick envelopes. A single PDR is not expected to have \(N(C^{+})\) in excess of a few \(\times 10^{17}\) cm\(^{-2}\). A scenario with a crowded population of PDRs overlapping along the line of sight is therefore more plausible. If a typical single OB stellar cluster emits up to 10\(^{39}\) erg s\(^{-1}\), the maximum value found by Scoville et al. (2001) in M51 and also the luminosity of W49, then the number of single clusters to produce the Mrk 231 starburst luminosity of 10\(^{12}\) \(L_{\odot}\) is \(\geq 4 \times 10^{6}\). If these clusters are concentrated in a disk of radius 460 pc and thickness 25 pc (DS98), the mean distance between neighbor clusters is only \(\lesssim 1.5\) pc (see also Keto et al., 1992). Merging of PDRs may be compatible with some area filling factor or, in some cases, some spiral structure is invoked within the disk.

In NGC 1068, Spinoglio et al. (2005) observed the OH 119 \(\mu\)m line in emission against the continuum. On the basis of a possible XDR chemistry, and given the corresponding mass, density, and temperature that characterize the nuclear region, Spinoglio et al. (2005) suggested that the OH 119 \(\mu\)m emission line could be formed in that region. This option also relied on the fact that relatively weak FIR emission is expected to arise from the circumnuclear disk of the Seyfert 2 galaxy, so that the OH 119 \(\mu\)m line can be excited through collisions and emit above the continuum in these dense and warm environments. The situation is different for Mrk 231 and Arp 220. In these ULIRGs, the extremely high luminosity arising from the nuclear region, together with the high concentrations of gas there, make the nuclear FIR emission component very bright. Any possible emission in the 119 \(\mu\)m line will be obscured by the strong absorption, which in these objects is \(\sim 30\) times stronger than the emission feature in NGC 1068. In addition, the strong FIR radiation density pumps high-lying OH and H\(_{2}\)O levels, thus producing absorptions in the higher-excitation lines. The OH and H\(_{2}\)O molecules are therefore potentially powerful tracers of circumnuclear regions around AGNs. Future Herschel observations of Mrk 231 and other sources will allow us to apply the models developed in this paper to these sources, refine them accordingly, and will certainly give new insights into the physical and chemical conditions of bright infrared galaxies.
