Over-expression of Plk4 induces centrosome amplification, loss of primary cilia and associated tissue hyperplasia in the mouse

To address the long-known relationship between supernumerary centrosomes and cancer, we have generated a transgenic mouse that permits inducible expression of the master regulator of centriole duplication, Polo-like-kinase-4 (Plk4). Over-expression of Plk4 from this transgene advances the onset of tumour formation that occurs in the absence of the tumour suppressor p53. Plk4 over-expression also leads to hyperproliferation of cells in the pancreas and skin that is enhanced in a p53 null background. Pancreatic islets become enlarged following Plk4 over-expression as a result of equal expansion of α- and β-cells, which exhibit centrosome amplification. Mice overexpressing Plk4 develop grey hair due to a loss of differentiated melanocytes and bald patches of skin associated with a thickening of the epidermis. This reflects an increase in proliferating cells expressing keratin 5 in the basal epidermal layer and the expansion of these cells into suprabasal layers. Such cells also express keratin 6, a marker for hyperplasia. Proliferating cells showed an increase in centrosome number and a loss of primary cilia, events that were mirrored in primary cultures of keratinocytes established from these animals. We discuss how repeated duplication of centrioles appears to prevent the formation of basal bodies leading to loss of primary cilia, disruption of signalling and thereby aberrant differentiation of cells within the epidermis. The absence of p53 permits cells with increased centrosomes to continue dividing, thus setting up a neoplastic state of error prone mitoses, a prerequisite for cancer development.

1. Introduction

The centrosome was first described almost simultaneously by Edouard van Beneden working in Liège and Theodor Boveri in Munich in 1887 (reviewed in [1]) as a structure at the poles of the mitotic spindle that persisted through the life cycle of the cell. Towards the end of the nineteenth century tumour cells were already observed to have multiple spindle poles, and now we know supernumerary centrosomes to be present in a wide range of solid and
haematological tumours, including pancreatic, ovarian, colon and prostate cancer, multiple myeloma, non-Hodgkin’s and Hodgkin’s lymphoma, and acute and chronic myeloid leukaemia [2–7]. Abnormalities have been detected at both early [8–10] and advanced stages of disease where they generally indicate poor prognosis [11]. Amplified centrosomes also correlate with metastasis of head and neck, prostate and breast tumours [12–14]. However, despite these long-known associations, the contribution of centrosomal amplification to oncogenesis remains unclear.

Centrosome number is normally tightly controlled within the cell division cycle. At the core of centrosomes lie the nine-fold symmetrical centrioles. Cells enter mitosis with two pairs of orthogonally arranged centrioles that separate to form the two centrosomes at the poles of the spindle. The centrioles disengage upon the completion of mitosis and enable both individual centrioles to initiate the duplication process. Centriole duplication is controlled by Polo-like-kinase-4 (Plk4) that phosphorylates the centriole protein Stil/Ana2 allowing it to recruit Sas6, the core component of the centriole cartwheel [15–18]. Elevating Plk4 expression through its ectopic expression or by eliminating the SCF ubiquitin-protein ligase required for Plk4 destruction results in the formation of multiple centrosomes [19–23].

The loss of centrosomes has different consequences in different organisms and tissues. Drosophila can tolerate centriole loss in some, but not all, tissues, allowing defective cell divisions to continue [23–27]. However, centrosomes also serve as basal bodies, the foundations of cilia and flagellae [28,29], and so are essential to fashion the fly’s sensory organs for correct physical coordination [24,30]. In mammalian cells, the physical removal of centrosomes prevents cell cycle progression but eventually centrosomes reform by a de novo pathway and the cell cycle resumes [31–33]. In the mouse, there is a greater reliance on centrosomes to generate primary cilia essential for many types of cell signalling. However, unlike mutants that lack cilia, mutant embryos deficient for the centriole component Sas4 and thereby lacking centrioles exhibit extensive apoptosis associated with elevated p53 expression [34]. Apoptosis was rescued in embryos double mutant for Sas4 and p53, thus identifying a p53-dependent apoptotic pathway triggered by loss of centrioles. This has been further supported by experiments to eliminate Plk4 activity from cultured cells using either an auxin-inducible degradation system or pharmacological inhibition of the enzyme using a small molecule, centrinone [33,35]. In both these cases, loss of Plk4 activity results in loss of centrioles and a p53-dependent arrest of cell cycle progression, the mechanism of which is not understood.

The consequences of Plk4 over-expression also vary in different organisms and in different cell types. Over-expression or stabilization of Plk4 in either cultured Drosophila cells or mammalian cells leads to multiple centrosomes [19,21–23,36] and in fertilized Drosophila eggs drives the formation of thousands of centrioles at the expense of the normal progression of nuclear division cycles [20]. Strikingly this also happens in unfertilized eggs in which centrioles have been naturally eliminated during oogenesis and in which there is no incoming sperm to provide a basal body. Thus, in this circumstance, centriole formation is entirely driven by Plk4. Moreover, elevated expression of Plk4, and indeed perturbation of centrosome function through several routes, can promote tumourigenesis in flies [37,38].

Correct centrosome behaviour is also required for the development of cerebral cortex of the mammalian brain. Deficiency of any of several centrosome components including Plk4 results in microcephaly [39–41]. To study the effects of elevating Plk4 expression in the mouse brain, Matthiens et al. [42] generated transgenic animals in which Plk4 expression could be activated in the central nervous system in response to a tissue-specific Cre-mediated recombination event. This led to a microcephaly-like condition that was ascribed to the poor clustering of amplified centrosomes leading to abnormal mitoses and consequent apoptosis. Cell death could be overcome by removing p53 function, leading to the accumulation of aneuploidy cells that would differentiate rather than proliferate.

We wished to examine the consequences of elevated Plk4 expression, and thereby centrosome amplification, in other tissues in the mouse. To have temporal control on the over-expression of Plk4, we have developed a mouse line in which Plk4 is under the control of a doxycycline-inducible promoter. Induction of Plk4 expression in this mouse leads to an early onset of tumour formation in p53 null mice, behavioural defects suggesting abnormalities of brain development in agreement with a previous study [39], and hyperproliferation of cells in the pancreas and in the skin. Here we focus upon characterizing defects in the skin of these animals and show that elevated Plk4 leads to amplification of centrosomes and loss of primary cilia. Together this leads to both hyperproliferation and uncontrolled differentiation of the basal epidermis. We discuss how these phenotypes can arise and how we might account for the enhancement of these phenotypes when the p53 gene is deleted.

2. Results

2.1. Elevated Plk4 expression dramatically advances the onset of tumour formation in p53-deficient mice

Centrosome amplification has been identified as a marker of poor prognosis of aggressive, drug-resistant tumours in breast, pancreatic and colorectal cancer patients [43,44], but the relationship of centriole amplification to oncogenesis is uncertain. To address this in a model system, we generated a transgenic mouse that allows the inducible over-expression of wild-type mPlk4, the master regulator of centriole duplication. The vector comprised the reverse-tetracycline-controlled transactivator (rtTA) linked to a tetracycline-responsive element (TRE) regulating expression of wild-type mPlk4 and was targeted to the ROSA26 locus. This enabled the inducible and reversible over-expression of Plk4 at any time of development in the resulting transgenic animals or in cultured cells derived from them (figure 1a). We designate the homozygous transgenic mouse harbouring the inducible extra copy of wild-type Plk4 as Plk4OE/ Plk4OE.

As p53 was reported to overcome both the cell cycle arrest associated with loss of centrosomes resulting from deletion of Sas4 or degradation or inhibition of Plk4 [33–35] and the cell death resulting from elevated Plk4 expression in the mouse brain [42], we were prompted also to determine the consequences of centrosome amplification induced by Plk4 over-expression in a p53 knockout (KO) background (from now on p53KO). These mice show accelerated tumour formation, behavioural defects and cell hyperproliferation associated with elevated Plk4 expression in several tissues.
including the pancreas and skin. Here we describe some key features of mice that are expressing elevated levels of Plk4 and focus upon how this affects development of the skin and pancreas.

We first wished to address the effects of Plk4 overexpression upon tumour formation and so carried out parallel studies on the viability of the Plk4OE/Plk4OE line with or without the addition of doxycycline (+DOX) to promote Plk4 over-expression. Plk4OE/Plk4OE and Plk4OE/Plk4OE (+DOX) mice remained healthy during the period of study. Litter sizes were reduced in Plk4OE/Plk4OE mice, but tumour formation was not observed during treatment with doxycycline (+DOX) to promote Plk4 over-expression. The differences observed between Plk4OE/Plk4OE; p53KO/p53KO (n = 80) and Plk4OE/Plk4OE; p53KO/p53KO (+DOX) (n = 14) survival curves are significant (**p < 0.01; Student’s t-test). (c) Proportions of sarcomas and lymphomas. Note that animals that developed sarcomas also showed lymphomas. (d) Architecture of thymus and lymph nodes is obliterated and replaced by sheets of large, round cells with vesicular nuclei (Vn, black arrows). Apoptotic cells were also present (Ap, black asterisk). (g) Multicentric high-grade large cell lymphoma. (f) Kidney has normal architecture but contains multifocal cortical interstitial and subcapsular infiltrates of large lymphocytes (Li). (h) Large sheets of lymphocytes (Li) attached to pericardial surface of heart wall. (h–j) These tumours are sarcomas isolated from Plk4OE/Plk4OE; p53KO/p53KO mice. Typically, large masses of cells extended into muscle fibre bundles (M) and into attached adipose surrounding nerves and blood vessels. (i) Higher magnifications of sarcomas showing pleomorphic and anaplastic cells. Examples of giant (G) or multinucleated (MM) cells are indicated. These tumours were found close to the front limbs with high percentage of mitotic cells (an average of 5–10/40× field). (k) Paraffin section of samples from sarcomas where stained to reveal γ-tubulin or acetylated-tubulin (green). DNA is shown in red. Three different samples were analysed and showed a high mitotic index (8.55 ± 2.53%, n = 1400 cells/sample) in agreement with histological analysis made after H&E staining. (l) Proportion of cells that show one pair or two pairs of centrioles per cell or show centriole/centrosome amplification (more than 2 pairs of centrioles). (m) Mitotic progression in sarcomas from cryostat sections. (n) Proportions of mitotic abnormalities in sarcomas. Quantification in (l–n) performed in three different sarcomas; 500–1000 cells analysed per sarcoma.

the first 35 weeks (figure 1b). We found that approximately one half of Plk4OE/Plk4OE; p53KO/p53KO mice on a doxycycline-free diet developed tumours by the age of 20 weeks and all had tumours by 35 weeks. This time course of tumour appearance parallels previous reports for p53 homozygous null mice [45]. Interestingly, when Plk4 over-expression was induced in the Plk4OE/Plk4OE; p53KO/p53KO mice by the addition of DOX from eight weeks onwards, tumour formation was accelerated; half of the mice developed tumours by 15 weeks and all died within 26 weeks (red line; figure 1b).

The tumours arising in Plk4OE/Plk4OE; p53KO/p53KO mice were highly similar whether or not doxycycline was administered and comprised mainly lymphomas and sarcomas (figure 1c). The lymphomas invaded a variety of tissues including the thymus, kidney and heart (figure 1d–g). However, a wide variety of sarcomas arose more frequently and earlier after Plk4 over-expression. All animals that succumbed to sarcomas also had lymphomas. The sarcomas were typically localized close to the front limbs and developed very rapidly within one week. These tumours had highly pleomorphic and anaplastic cells that displayed a high incidence of mitosis (an average of 5–10 mitotic figures per 40× field) suggesting they are highly malignant (figure 1h–j) and centrosome amplification was detected in 34.79±5.48% of cells from sarcomas (figure 1f). The mitotic figures in these Plk4 over-expressing tumour cells were typically bipolar with multiple centrosomes at the poles (71%). Centrosome clustering was lost in 12.7±10.7% of prometaphase cells that were multipolar (figure 1k–n). Although we failed to detect any multipolar anaphases, we found chromatid lagging in 23.4±10.6% of anaphase figures (figure 1n). It will be of future interest to identify and characterize the mesenchymal cells in which these tumours arise.

We conclude that Plk4 over-expression significantly advances the onset of tumour formation in p53 null mice and that this is associated with an increased frequency of mitoses that generate aneuploid cells characteristic of many tumours.

2.2. Elevated Plk4 expression induces hyperproliferation of cells in the pancreas

The above findings raised the question of whether we could identify any tissues exhibiting common cellular changes that could be associated with events anticipating tumour development particularly in the absence of p53 function. Systematic histological examination of the tissues of Plk4OE/Plk4OE mice revealed that although pancreases had normal lobular architecture with intact acinar cell clusters, there was enlargement of the islets of Langerhans when over-expression of Plk4 was induced (figure 2a–c,e). The diameter of the islets was increased by approximately 30% and the density of cells within the islets more than doubled under these conditions (figure 2e–f). To determine whether this reflected differential proliferation of the major two endocrine cell types, we stained pancreas sections with antibodies against glucagon and insulin to detect α- and β-cells, respectively. This revealed a proportionate increase in the number of both glucagon- and insulin-positive cells following induction of Plk4 over-expression (82.8±6.7% β-cells versus 79.8±6.0% in Plk4OE/Plk4OE islets without and with DOX, respectively; figure 2d–f). Because loss of p53 is known to exacerbate the effects of both decreased and increased centrosome number [33,35,42], we also examined the effects of Plk4 over-expression on the pancreas in p53 null mice. Plk4 over-expression now resulted in a more than doubling in the diameters of the islets although the cell density was not as high as when p53 was present (figure 2g,f). Again, there was an increase in both α- and β-cells in similar proportions (89.8±3.2% β-cells versus 85.5±3.1% in Plk4OE/Plk4OE, p53KO/p53KO without and with DOX). The size of the islets directly correlated with the levels of Plk4 transcripts (figure 2g) and immunostaining of the islets revealed elevated Plk4 protein following treatment of the mice with doxycycline (figure 2g,h,j) and an increase in centrosome number (figure 2h,i). Plk4 was present in punctate bodies corresponding to centrosomes, and these increased in the number from one such body in non-doxycycline-treated, p53 +/+ cells to four or more in p53 null cells over-expressing Plk4 (figure 2j). Thus, elevated expression levels of Plk4 and higher centrosome numbers correlate with hyperproliferation of α- and β-cells in the pancreas that is exacerbated in the absence of p53.

2.3. Elevated Plk4 over-expression affects melanocyte differentiation

A striking feature of the Plk4OE/Plk4OE mice was skin lesions that include alopecia at the time of weaning followed by regrowth of hair around one month after birth. Animals that did not lose hair had grey coats (figure 3a,b). Most of the grey hair did not persist and there was a regain of some black fur within the first month. This phenotype led us to examine the effects of Plk4 over-expression upon melanocytes and the melanin pigment produced by them. Melanocytes are located in the interfollicular epidermis and within hair follicles, and differentiate from neural-crest-derived melanocyte stem cells (MSCs). These MSCs are intermingled with hair follicle stem cells in the bulge and the hair germ. Differentiated melanocytes produce and transfer melanin to the adjacent keratinocytes during the anagen (growth) phase of the cyclical process of hair regeneration (reviewed in [46]). Using Fontana-Masson staining, we found a reduction of melanin granules in the bulge of 2-day-old Plk4OE/Plk4OE mice and their apparent absence from follicles, both in a wild-type or p53KO/p53KO background (figure 3d). We also stained skin sections to examine melanin distribution at 20 days. This revealed a reduction in melanin in Plk4OE/Plk4OE mice irrespective of whether animals were treated with doxycycline and that was accentuated if the animals were also null for p53 (figure 3e). As an alternative way to assess melanin production, we determined the relative levels of transcripts for tyrosinase, the enzyme catalysing the first step in melanin synthesis and which is expressed in melanocytes [47]. Tyrosinase mRNA was reduced both in untreated Plk4OE/Plk4OE mice that show some elevation of basal Plk4 mRNA levels and following doxycycline treatment to induce Plk4 expression. Tyrosinase transcripts were further reduced in a p53 null background (figure 3c). Taken together these observations point to reduced melanin biosynthesis in response to elevated Plk4, an effect enhanced in the absence of p53 so accounting for the grey hair of the animals.

We then wanted to determine whether the grey hair was a consequence of reduced melanin production or a reduced
Figure 2. Plk4 over-expression leads to hyperplasia of the pancreatic islets. (a–c) Haematoxylin–eosin-stained sections of mouse pancreas. (a) Control (+/+) pancreas shows normal acinar cells (AC), islets of Langerhans (I) and lobular architecture. (b) Pancreas of Plk4OE/Plk4OE (+ DOX) male has normal lobular architecture, intact acinar cell clusters within lobes and islets of variable size. Lymphocytes are seen surrounding islets and between clusters of acinar cells (black arrows). (c) Pancreas from a Plk4OE/Plk4OE; p53KO/p53KO male showing normal lobular architecture and very large islets. (d) Immunofluorescence of pancreas cryosections showing β-cells detected by anti-insulin (red) and α-cells detected by anti-glucagon (green) in islets. DNA is blue. (e) Diameter of islets (mean ± s.d., n = 12) in mice of indicated genotypes without or with (+ DOX) doxycycline treatment. (f) Density of insulin or glucagon-positive cells (mean ± s.d., n = 12) in islets of indicated genotypes without and with doxycline (+ DOX) treatment. (g) Q-RT-PCR analysis of relative levels of Plk4 transcripts in pancreatic extracts of indicated genotypes without or with (+ DOX) doxycycline treatment. Average from three biological samples (three replicates for each). (h) Proportion of cells showing 1 (one pair of dots), 2 (two pairs of dots) centrosomes or centrosome amplification (more than two pairs of dots) in pancreatic islets. Significance was determined by Student’s t-test. *p < 0.05, **p < 0.01, ***p < 0.005.
Figure 3. Plk4 over-expression leads to loss of hair and its pigmentation. (a) Plk4+/Plk4OE; p53−/−p53−/− mouse exhibiting typical hair loss phenotype. (b) Plk4OE/Plk4OE; p53−/−p53−/− mice showing varying degrees of greying hair. (c) Q-RT-PCR analysis of Plk4 and tyrosinase transcripts in extracts of total back skin from mice of indicated genotypes and treatment indicating mean ± s.e. for three independent biological samples and three replicates/sample (+DOX indicates doxycycline treatment). (d) Fontana-Masson staining of cryosections of P2 back skin from mice of indicated genotypes. +DOX indicates treatment with doxycycline. (e) Fontana-Masson staining of P20 back skin cryosections from mice of indicated genotypes and treated with doxycycline where indicated (+DOX). (f) Anagen hair follicle in wild-type back skin immunostained to reveal melanocyte markers KIT (red in merge; white, monochrome), MITF (green) and DCT (blue in merge; white in monochrome). DNA is represented in white. Differentiated melanocytes identified by triple KIT+MITF+DCT+ staining. (g) P2 back skin from Plk4OE/Plk4OE mice without or with Plk4 over-expression (+DOX) showing anagen hair follicle immunostained to reveal melanocyte markers KIT (red in merge; white in monochrome), MITF (green) and DCT (blue in merge; white in monochrome). DNA is white in merge. Note reduction in differentiated melanocytes identified by triple KIT+MITF+DCT+ positive immunostaining. (h) P2 back skin from Plk4OE/Plk4OE; p53−/−p53−/− mice without or with Plk4 over-expression (+DOX) showing hair follicles immunostained for melanocyte markers KIT (red in merge; white in monochrome), MITF (green) and DCT (blue in merge; white in monochrome). DNA is white in merge. Differentiated melanocytes (KIT+MITF+DCT+) are reduced in Plk4OE/Plk4OE; p53−/−p53−/− (+DOX) mice. (i) Mean numbers ± s.d. of differentiated melanocytes (KIT+MITF+DCT+) per bulb in indicated genotypes and treatments. Significance determined by Student’s t-test. *p < 0.05, **p < 0.01 and ***p < 0.005.
number of melanocytes undergoing activation/differentiation. To this end, we carried out immunofluorescence upon cryosections of the back skin of animals 2 days after birth (P2) to detect the MSC population undergoing differentiation (figure 3f–i). The tyrosine kinase receptor, c-KIT and dopachrome tautomerase (DCT) are hallmarks to identify the MSC population (reviewed in [46]). MSCs co-expressing Kit and microphthalmia-associated transcription factor (MITF), the master regulator of melanocyte differentiation (reviewed in [46]), identify the differentiated melanocyte subpopulation. We found a reduced number of KIT"MITF"DCT" cells in the bulge when Plk4 was over-expressed, particularly in a p53KO/p53KO background (figure 3i). This population is responsible for pigmentation of growing hair. However, the number of MSCs (expressing DCT and KIT) in the bulge that will renew the melanocyte population in subsequent hair cycles did not vary significantly between the different genotypes and treatments (an average of 4.35–5 KIT"DCT" cells per bulge). This strongly suggests that Plk4 over-expression compromises melanocyte differentiation and subsequent melanin synthesis.

2.4. Plk4 over-expression affects cell proliferation in epidermis

The above experiments also revealed a thickening of the epidermis and some apparently invaginated hair follicles when Plk4 levels were elevated in Plk4OE/Plk4OE; p53KO/P53KO mice. Thus, we decided to explore the epidermal phenotype in greater detail. The epidermis is a stratified structure containing self-renewing stem cells within the basal layer that express keratins 5 and 14 (K5, K14) and that through delamination and/or asymmetrical cell division give rise to non-proliferative, spinous and granular layers (expressing keratins 1 and 10 (K1, K10) and involucrin) and outer layers of terminally differentiated stratum corneum cells (reviewed in [48]). The increased cell density within the epidermal basal layer of Plk4 over-expressing samples (figure 3e) prompted us to ask whether cell proliferation was affected as a result of increased levels of Plk4.

To address whether there was an increased number of cycling cells within the basal epidermis, we analysed skin from 2-day-old pups (P2) and 20–day-old pups (P20) using Ki67 as a marker for proliferating cells (figure 4a–c). In wild-type skin (+/+) K67-positive cells are solely found in the basal layer, as these are the only cycling cells in unper- turbated circumstances (figure 4a). We found Ki67-positive cells in the basal layer did not increase significantly following doxycycline treatment of Plk4OE/Plk4OE mice (n = 300/sample; 59.5 ± 19.4% in Plk4OE/Plk4OE; p53KO/P53KO versus 63.9 ± 9.4% in control (+/−)). However, in the skin of Plk4OE/Plk4OE; p53KO/P53KO mice, doxycycline treatment also led to the appearance of Ki67-positive cells in the super- basal layers (n = 425 cells/sample, 7.40 ± 3.90%) within 2 days after birth (asterisk in figure 4a). We also examined the distribution of keratin 6 (K6), which is normally restricted to the hair follicles but is also found in the interfollicular epidermis in conditions of hyperplasia the epidermis [49,50]. Strikingly, we found that K6 was widely expressed in basal and suprabasal cells after induction of Plk4 expression in either a wild-type or p53 null background (arrowheads in figure 4a). Whereas in normal skin there is a clear separation between basal (K5-positive cells) and suprabasal (K10-positive cells) layers, induction of Plk4 expression in either a wild-type or p53 null background led to an expansion of K5-positive cells. This was particularly evident in Plk4OE/Plk4OE; p53KO/P53KO doxycycline-treated mice at 20 days (figure 4d), where both K67- and K5-positive cells were significantly expanded to suprabasal layers and K6 staining extended to most of the epidermis and hair follicles. There was also an increase in the number of cells expressing the early differentiation marker, K10.

The above findings were mirrored by the quantitation of mRNA levels for these markers. Over-expression of Plk4 in a p53 null background led to a notable increase in the expression of the basal marker K14 and a reduction in mRNA levels for involucrin, filaggrin and loricrin, markers of late stages of differentiation (figure 4b). We also found a reduction of the transcript levels of ΔNp63, a p53 family member that controls expansion of epidermal cells and promotes differentiation [51] (figure 4c). This, together with a similar reduction in expression of the Cdk inhibitor p21 (mp21; figure 4c), is compatible with delayed terminal differentiation [52–54]. In agreement, with these results, percentage of Ki67-positive cells is significantly increased in Plk4OE/Plk4OE; p53KO/P53KO doxycycline-treated mice at 20 days, suggesting increased proliferation sustains the higher number of suprabasal cells in these samples compared to control (figure 4e,f).

Taken together our findings indicate that elevated expression of Plk4 results in hyperproliferation of the epidermis. Specifically, we observed an expansion of basal progenitor cells in suprabasal layers and a decreased expression of genes associated with terminal differentiation. These observations accord with the thickening of the epidermis and disrupted hair follicle morphology as a consequence of Plk4 over-expression.

2.5. Plk4 over-expression induces centriole over-duplication and primary cilia disappearance in epidermis

We next considered whether the alterations we had observed in the regulation of cell proliferation and differentiation in the epidermis could reflect changes mediated by elevated Plk4 upon the centrosomes and/or primary cilia, both of which rely upon centrioles for their correct formation and function. To this end, we stained skin sections to reveal acetylated α-tubulin, a marker of the primary cilia, and Plk4 itself, which associates with centrioles, either in basal bodies or centrosomes. In the skin of wild-type mice, the great majority of cells of the basal epidermis showed bodies of Plk4 staining associated with the base of single primary cilia (figure 5a). Over-expression of Plk4 during development led to increased numbers of centrosomes in the basal epidermis and a loss of primary cilia (figure 5a,c). Loss of primary cilia and mis-positioning of centrosomes was particularly dramatic when Plk4 over-expression occurred in a p53 null background (12.2 ± 4.3% of cells with primary cilia in Plk4OE/Plk4OE; p53KO/P53KO (±DOX) versus 35.3 ± 4.9% in Plk4OE/Plk4OE; p53KO/P53KO; figure 5a,c). We were still able to observe some residual primary cilia in hair follicles even though these cells had extra centrioles (figure 5b). However, consistently, only a single primary cilium was formed (figure 5b), and these cilia were longer than those in wild-type cells (figure 5d). Thus, the effects of elevated Plk4 may differ in
Figure 4. Plk4 over-expression leads to hyperproliferation and abnormal differentiation of cells in suprabasal layers. (a) Immunofluorescence of cryosections of P2 back skin from mice of indicated genotypes treated with doxycycline as indicated (+DOX). Note: Ki67 reveals proliferating cells in basal and suprabasal (white asterisk) epidermal layers of Plk4OE/Plk4OE; p53KO/p53KO (+DOX) mice; K6, restricted to hair follicles in controls, is present in epidermis following Plk4 induction (arrowheads). Basal layer marker K5 present throughout epidermis following Plk4 induction; distribution of early differentiation marker, K10 not affected and does not reveal differences between the experimental samples and the control at this stage. B, basal; Der, dermis; Epi, epidermis; Sp, suprabasal; dotted lines, dermo-epidermal border. (b) Quantitative RT-PCR assays for levels of indicated transcripts in total back skin from 2 day pups of indicated genotypes and treatment (n = 3 and three replicates for each sample). Note: elevated Plk4 transcripts consistently correlate with low expression of late differentiation genes filaggrin (Fla), involucrin (Inv) and loricrin (Loc). (c) Quantitative RT-PCR assays as in (b) for P21 (mp21) and ΔNP63. (d) Immunofluorescence analysis of back skin from 20 day pups of indicated genotypes and treatment. Note: Ki67-positive cells in basal and suprabasal cells (arrowheads) and K6 in multiple layers co-localizing with K5 (white arrow) in Plk4OE/Plk4OE; p53KO/p53KO (+DOX) mice; expanded staining of K5 and K10. (e) Ratio of basal to suprabasal cells indicated as mean ± s.d. (f) Proportion of cycling cells in epidermis. Mean ± s.d. % of cells showing Ki67-positive immunostaining. Significance determined by Student’s t-test. *p < 0.05.
Figure 5. Over-expression of Plk4 leads to multiple centrosomes and loss of primary cilia. (a) Immunostaining of back skin of P2 pups of indicated genotypes and treatment to reveal Plk4 (red), acetylated tubulin (green) and DNA (blue). Arrows indicate individual primary cilia (anti-acetylated tubulin) that are apically oriented in basal and suprabasal cells in wild-type control. Note: induction of Plk4 leads to extra centrioles and loss of primary cilia. (b) Immunostaining of hair follicles in mice of indicated genotypes and treatment. Note: primary cilia (arrowheads) are still observed in hair follicles after Plk4 induction although they appear longer than in control. (c) Quantification of centriole pairs in basal and superbasal layers. Mean ± s.d., n = 30–50 cells/condition. (d) Quantification of primary cilium length in samples illustrated in (b). Mean ± s.d., n = 30–50 cells per condition. Significance determined by Student’s t-test. **p < 0.01, ***p < 0.005.
different cell types. In the majority of cells of the basal epidermis, Plk4 over-expression results in elevated numbers of centrosomes that form at the expense of primary cilia. This correlates with the increased proliferation of these cells. A primary cilium is still able to form alongside additional centrosomes that form at the expense of primary cilia. This mis, Plk4 over-expression results in elevated numbers of centrosomes and loss of primary cilia in primary keratinocytes. (Figure 6).

We then prepared primary cultures of keratinocytes from our mouse lines as these can be cultured under conditions that permit either cell proliferation or, following the addition of calcium, the formation of cell–cell contacts and cellular differentiation. Induction of Plk4 over-expression following addition of doxycycline to primary Plk4OE/Plk4OE-derived keratinocytes cultured in low concentrations of calcium reproducibly resulted in centriole over-duplication. (figure 6a,b). By 48 h after addition of calcium, adherens junctions formed and tight junctions and desmosomes were assembled. Such cells expressed markers of early and late differentiation and grew on top of each other to form a pseudo-three-dimensional epidermis. Under these conditions, a single primary cilium formed at the surface of approximately 40% of cells in either wild-type control cells or in Plk4OE/Plk4OE cells without Plk4 induction. Addition of doxycycline to the medium promoted the formation of supernumerary centrosomes

---

**Figure 6.** Over-expression of Plk4 leads to multiple centrosomes and loss of primary cilia in primary keratinocytes. (a) Primary culture of keratinocytes isolated from Wt, Plk4OE/Plk4OE and Plk4OE/Plk4OE, p53KO/p53KO dorsal skin under low calcium conditions. Plk4 over-expression promoted by addition of doxycycline (DOX). Immunostaining reveals Plk4 (red), centrin 2/3 (green) and γ-tubulin (blue). DNA stained with DAPI (white). Individual regions magnified in insets showing example of centriole over-duplication after Plk4 over-expression. (b) Quantitation of centrioles in three independent experiments. Mean values ± s.d.; more than 200 cells quantified for each condition. (c) In vitro, addition of Ca²⁺ induces primary cilia formation in control, Plk4OE/Plk4OE and Plk4OE/Plk4OE; p53KO/p53KO. In control conditions formed and tight junctions and desmosomes were assembled. Such cells expressed markers of early and late differentiation and grew on top of each other to form a pseudo-three-dimensional epidermis. Under these conditions, a single primary cilium formed at the surface of approximately 40% of cells in either wild-type control cells or in Plk4OE/Plk4OE cells without Plk4 induction. Addition of doxycycline to the medium promoted the formation of supernumerary centrosomes.

---

See the image of additional figures and tables for further details.
and the formation of fewer primary cilia (figure 6b,c). When a primary cilium was formed, there was only one per cell even though multiple centrioles could be present. Moreover, these primary cilia were significantly longer than in wild-type cells or Plk4<sup>OE/OE</sup>/Pik4<sup>OE/OE</sup> cells that had not been induced to over-express Plik4 (figure 6d).

Thus, over-expression of Plik4 results in supernumerary centrosomes both in cells of the basal epidermis and in cultures of primary keratinocytes. In both cases, cells appear to fail to leave the proliferative state and they fail to form primary cilia. This suggests that over-expression of Plik4 leads to an alteration in the balance between proliferation and differentiation of the progenitor epidermal cells. Cilia formation could be compromised either directly by the increased number of centrosomes or as a consequence of a failure of cells to cease cycling sufficiently to enable ciliogenesis. It is known that the primary cilia receive and transmit extracellular signals during development [55–57] and that several ciliary mutants display defects in the commitment of progenitors to differentiate. It is also known that lack of primary cilia in cells of the basal epidermis would compromise the signalling events required to promote their correct differentiation [58,59], so accounting for the defects that we see in cell differentiation in the skin of Plik4 over-expressing mice.

### 3. Discussion

The great majority of tumour cells are both aneuploid and have multiple centrosomes [7,8,60], leading to the suggestion that these properties may be causally related. However, the extent to which chromosome instability resulting from multiple centrosomes contributes to tumour formation is not clear because centrosome clustering at mitosis usually ensures the fidelity of chromosome transmission on bipolar spindles [61]. The transgenic mouse we have generated allows us to induce centriole duplication in response to elevated Plik4 and so begin to address the relationship between multiple centrosomes and tumour formation. Our findings that elevating Plik4 perturbs the balance between proliferation and differentiation in different tissues in a manner exacerbated by loss of the p53 tumour suppressor gives the potential to identify links between supernumerary centrosomes and early steps in tumourigenesis.

Mice deficient for p53 are susceptible to tumour formation [62] and, moreover, the embryonic fibroblasts established from such mice show supernumerary centrosomes [63]. One interpretation of these findings has been that p53 might mediate cell cycle arrest in response to increased centrosome numbers as part of a tetraploidy checkpoint to monitor completion of cytokinesis [64] or by monitoring DNA damage or spindle defects in these cells [65–67]. Others have proposed a direct role for p53 in directly regulating centrosome duplication [68–70]. While it remains difficult to distinguish cause from effect, growing evidence points towards a p53-mediated response to changes in centrosome integrity that receives support from our present study and earlier findings. P53 deletion overcomes either the block to cell progression or apoptosis resulting from depletion of several different centrosome proteins in cultured cells [71] or centriole loss in Sst4 knockout mouse embryos [34]. Moreover, recent studies have identified a p53 response that is triggered by the inhibition or the destruction of Plik4 that prevents centriole duplication [33,35]. DNA damage, stress, chromosome mis-segregation, prolonged time in mitosis [33,35], nor the Hippo-signalling pathway, recently shown to respond to cytokinesis failure [72], were responsible for triggering this p53-dependent arrest in a senescent-like G1 state in response to centrosome loss. We now show that defects in the pancreas and skin resulting from Plik4 over-expression are enhanced by the loss of p53. We do not know the nature of this p53-dependent response to either gain or loss of centrosomes but it seems possible that it uses a common pathway as both situations can perturb spindle organization and dynamics and cell cycle progression.

The tumour formation that we observe, however, appears dependent upon the loss of p53 function; it is exacerbated by Plik4 over-expression but is not seen following Plik4 over-expression alone. It will be important in future studies to identify the origins of these tumour cells, particularly the sarcomas that appear with increased frequency when Plik4 levels are elevated. That we see tissue hyperplasia rather than neoplasia in the pancreas and skin might reflect the time course of the development of different tumour types in the absence of p53. Usually, p53 null mice first develop lymphomas and most do not survive for long enough for sarcomas to arise. Nevertheless, sarcoma formation predominates in mice in which lymphocytes have been genetically eliminated and it is conceivable that the development of carcinomas, as would occur in the skin, would be masked by these earlier events of lymphoma and then sarcoma formation [73].

The hyperplasia we observe in the pancreas in response to elevated Plik4 and enhanced in the absence of p53 appears to affect the differentiated endocrine cells equally. Thus, the enlarged islets of Langerhans maintain similar proportions of α- and β-cells suggesting that both populations have proliferated and differentiated. In the skin, on the other hand, elevated Plik4 permits proliferating cells to expand into the suprabasal layers of the epithelium where they show inappropriate expression of differentiation markers. This too is enhanced in a p53 background. The shift in the balance of cell proliferation and differentiation could reflect persistence of the centriole as a structure associated with the centrosome and so keeping the cell prepared for cell division. It could also result from a loss of barrier function due to the disruption in the stratified epidermal architecture as occurs, for example, in the inflammatory response (reviewed in [74]). The stratification of the skin occurs when polarized cells of the basal epidermis undergo divisions perpendicular to the basal cell layer to produce the differentiating upper layers [75]. Multiple centrosomes might affect the orientation of mitotic spindles thus perturbing the mechanism that delivers cells from the basal to the suprabasal layers in an orderly manner.

Alternatively, the abnormal differentiation in Plik4 over-expressing, p53 null cells could reflect loss of primary cilia that we observe to reciprocate additional centrosome formation both in cells of the basal epidermis and in cultures of primary keratinocytes established from this skin. The differentiation of cells entering the spinous layer is a Notch signalling-dependent process [76] and a failure of ciliogenesis has been reported to compromise Notch signalling and result in defective epidermal differentiation [58]. Thus, in the absence of sufficient primary cilia, the signalling pathways required for correct differentiation would be defective. Reduced signalling activity was also previously reported in cultured cells expressing elevated levels of Plik4 [77]. However, in the examples studied by these authors, cells with extra centrosomes often...
formed more than one primary cilium. These cilia were associated with reduced concentrations of signalling molecules and this appeared to be responsible for the reduction in signalling activity. This contrasts to our findings in keratinocytes where supernumerary centrosomes appear to form at the expense of the formation of cilia. The occasional cell that we do find with two primary cilia of increased length seems at odds with these earlier findings. The net outcome of disrupted signalling is the same although in one case it appears to be the consequence of the inefficient operation of the signalling machinery and in the other through the loss of the mechanical apparatus, the cilium themselves.

In addition to the work we now report, another study has described a p53-dependent response to mitotic abnormalities resulting from Plk4 over-expression in the developing mouse brain [42]. These authors described how this led neural stem cells to undertake multipolar mitoses leading to aneuploid cells. Our study also seems to support a p53-dependent response to mitotic abnormalities, with Plk4 overexpression resulting in cells that were directed to p53-dependent apoptosis. They reported that loss of p53 allowed aneuploid cells to accumulate and differentiate thereby reducing the proportion of proliferating cells and reducing brain size. These consequences seem to differ from the ones we now report in the pancreas and skin where p53 enhances the effects of Plk4 over-expression by allowing cells to proliferate. This suggests that the responses to the supernumerary centrosomes resulting from over-expression of Plk4 might differ in different tissues.

Our study highlights the importance of the p53 pathway in monitoring defects elicited by the elevated expression of Plk4. The increase in centrosome numbers and decrease in primary cilia strongly suggest that the effects we observe reflect the principal function of Plk4 to drive centrosome duplication, although we cannot at this stage exclude an involvement of Plk4 in regulating other aspects of cellular physiology (e.g. [78,79]). Further studies are now required to dissect out the precise manner by which elevated Plk4 affects cell cycle progression and cellular architecture, how these might affect the differentiation programme of the cell and how this could contribute to tumour development.

4. Material and methods

4.1. Generation of mESCs inducibly expressing Plk4 from the Rosa26 locus

The rtTA gene and response element (ClonTech) were cloned into a Rosa26 targeting vector [80] upstream of Gateway elements attR1/attR2. mPlk4 cDNA flanked by attL1/attL2 sites was introduced into the vector by Gateway cloning (Life Technology), yielding a Rosa26 targeting vector harbouring tetracycline-inducible cDNA for Plk4. Primers used for subcloning the mousePlk4cDNA were mPlk4RosaFor and mPlk4RosaRev (table 1). The targeting vector was introduced into JM8 mESCs by electroporation, and successfull targetings were confirmed by long-range PCR across the 5′ homology arm of clonal puromycin-resistant cell lines.

4.2. Histological analysis of skin and pancreas

Samples were fixed in 4% paraformaldehyde in PBS at 4°C overnight and then dehydrated and embedded in paraffin wax. Eight micrometre sections were stained with haematoxylin and eosin for histological analysis. Samples from dorsal skin or pancreas were washed in PBS, embedded in OCT compound and kept at -80°C prior to cryosectioning for immunofluorescence.

4.3. Fontana-Masson staining

Fontana-Masson staining of backskin cryosections was performed following the protocol provided in the Fontana-Masson kit (Abcam, ab150669).

4.4. Culture of keratinocytes

Mouse keratinocytes were isolated from the backskin of 2-day-old pups from each genetic background using dispase and trypsin. After filtration in 40 μm cell strainers, cells were either fixed in 2 mM Ca²⁺ or cultures were shifted to 2 mM Ca²⁺ media for 48 h to analyse cytoskeleton and primary cilia formation.

4.5. Antibodies

Primary antibodies were obtained from the following sources: rabbit anti-Cep192 [82] (1:1000), rabbit anti-keratin 5 ab52635 (Abcam, 1:1000), chicken anti-keratin 5 #905901 (BioLegend, 1:1000), rabbit anti-keratin 10 ab76318 (Abcam, 1:1000), rabbit anti-keratin 6 #903701 (BioLegend, 1:1000), rabbit anti-Cit ab5506 (Abcam), rabbit anti-Ki67 ab15580 (Abcam, 1:500), mouse anti-γ tubulin monoclonal GTU-88.
(Sigma, 1 : 200), rabbit anti-γ-tubulin T3559 (Sigma, 1 : 500), rat anti-PLK4 [78] (1 : 1000), mouse anti-centrin2/3 S3332 (Santa Cruz Biotechnology, 1 : 500), guinea-pig anti-insulin ab7842 (Abcam, 1 : 50), mouse monoclonal anti-glucagon ab10988 (Abcam, 1 : 200), mouse monoclonal anti-acetylated-tubulin clone-6-11B-1 (Sigma, 1 : 200), mouse anti-MITF ab80651 (Abcam, 1 : 200), rabbit anti-DCT ab74073 (Abcam, 1 : 200), rabbit anti-E-cadherin clone ECDD-2 (Invitrogen, 1 : 200), rat anti-mouse-cKit clone 2B8 (Biolegend). Secondary antibodies used (1 : 2000 for immunofluorescence) were conjugated with Alexa 488, Alexa 568 or Alexa 647 (Invitrogen) and had minimal cross-reactivity to other species.

4.6. Fixation protocol for tissues and cells

For identification of centrosomal proteins by immunofluorescence, preparations were fixed (12 min in ice-cold methanol), quickly rinsed in 1 × PBS and then permeabilized in 1 × PBS; 0.1% Triton-X100 for three times, for 5 min each. Preparations were blocked with 1 × PBS; 0.1% Tween 20; 10% FBS for 1 h, followed by primary antibody incubation in the same solution for at least 2 h at room temperature. Washes were performed in 1 × PBS; 0.1% Tween 20 for 30 minutes before the addition of secondary antibody in 1 × PBS; 0.1% Tween 20 with 10% FBS. Preparations were washed as previously, mounted in Vectashield with DAPI and sealed.

4.7. Microscopy

Images were collected on a Zeiss LSM 510 Meta Laser Scanning Confocal Microscope using 63X/1.4 or 100X/1.4 oil objectives, and the LSM 510 v. 4.2 software. Images were deconvolved using HUYGENS PROFESSIONAL software; processing and analysis was performed with IMAGEJ v. 1.50b and Adobe PHOTOSHOP CS5.

4.8. RT-qPCR conditions

RNA was isolated from the different tissues with RNAqueous Kit (Ambion) and RT-qPCR was performed using Power SYBR® Green RNA-to-CT™ 1-Step Kit (Life Technologies) on a Stepone Plus 96 RT system (Life Technologies) with GAPDH as reference gene. Primers pairs (forward and reverse) used for each gene are indicated in table 2. Specificity was confirmed by subsequent melting curve analysis or gel electrophoresis. Levels of PCR product were expressed as a function of GAPDH. Reactions were performed in triplicate for at least three biological samples and fold changes calculated using the 2−ΔΔCT method.

Title:
Over-expression of Plk4 induces centrosome amplification, loss of primary cilia and associated tissue hyperplasia in the mouse.

Date:
2015-12
