Abstract

Background
Drug-related emergency department (ED) visits are escalating, especially for stimulant use (i.e., cocaine and psychostimulants such as methamphetamine). We sought to characterize rates, presentation, and management of US ED visits related to cocaine and psychostimulant use, compared to opioid use.

Methods
We used 2008–2018 National Hospital Ambulatory Medical Care Survey data to identify a nationally representative sample of ED visits related to cocaine and psychostimulant use, with opioids as the comparator. We excluded visits related to ≥2 of the three possible drug categories. We estimated annual rate trends using unadjusted Poisson regression; described demographics, presenting concerns, and management; and determined associations between drug-type and presenting concerns (categorized as psychiatric, neurologic, cardiopulmonary, and drug toxicity/withdrawal) using logistic regression, adjusting for age, sex, race/ethnicity, and homelessness.

Results
Cocaine-related ED visits did not significantly increase, while psychostimulant-related ED visits increased from 2008 to 2018 (2.2 visits per 10,000 population to 12.9 visits per 10,000 population, p < 0.001). Cocaine-related ED visits had higher usage of cardiac testing, while psychostimulant-related ED visits had higher usage of chemical restraints than opioid-related ED visits. Cocaine- and psychostimulant-related ED visits had greater odds of presenting with cardiopulmonary concerns (cocaine adjusted odds ratio [aOR] 2.95, 95% CI 1.70–5.13; psychostimulant aOR 2.46, 95% CI 1.42–4.26), while psychostimulant-related visits had greater odds of presenting with psychiatric concerns (aOR 2.69; 95% CI 1.83–3.95) and lower odds of presenting with drug toxicity/withdrawal concerns (aOR 0.47, 95% CI 0.30–0.73) compared to opioid-related ED visits.

Conclusion
Presentations for stimulant-related ED visits differ from opioid-related ED visits: compared to opioids, ED presentations related to cocaine and psychostimulants are less often identified as related to drug toxicity/withdrawal and more often require interventions to address acute cardiopulmonary and psychiatric complications.

Introduction
Emergency department (ED) visits related to drug overdose are escalating, especially during the COVID-19 pandemic. While national attention has focused on opioids in the escalating overdose crisis, hospitals and EDs across the United States (US) are also facing an expanding burden of visits related to stimulant use. Stimulant-related ED visits are largely attributed to the use of controlled substances such as cocaine and psychostimulants (e.g., methamphetamine). Cocaine has been a major contributor to stimulant-related harms since at least 2011, though in recent years, the US has seen a surge in methamphetamine use and related complications. In addition to stimulant-related ED visits increasing nationwide, stimulant-related overdose deaths have also rapidly increased since 2010. Overdose deaths from stimulants now outnumber overdose deaths attributed to prescription opioids and heroin.

Prior ED studies have mostly focused on ED visits related to stimulant overdose. However, acute stimulant toxicity is not always recognized as an overdose due to symptom variability, and these studies do not address ED visits related to chronic complications of drug use. There is a need to broadly examine the characteristics, presentations, and clinical management of all stimulant-related ED visits, not only visits that are identified as related to overdose. Presentations from stimulant toxicity also show wide variability, affect multiple organ systems, and are not as readily attributed to substance use. Cocaine toxicity is strongly associated with cardiovascular complications, while psychostimulant toxicity is also associated with cardiac complications, as well as acute psychosis and agitation. Little is known about which presenting concerns dominate for psychostimulant-related ED visits, and few studies have examined how ED presentations for cocaine and psychostimulant use vary compared to opioid use. A better understanding is needed, as how patients present to ED visits has significant implications on clinical management and ED resource utilization.

We sought to describe the annual trends and characteristics of cocaine- and psychostimulant-related ED visits, with opioids-related ED visits as the comparison group. We also evaluated whether chief presenting concerns during ED visits differ between these groups of drug-related ED visits.

Methods
Study design and setting
We conducted a secondary analysis using 2008–2018 data from the National Hospital Ambulatory Medical Care Survey (NHAMCS), a federally funded, nationally representative dataset of ED visits collected annually by the Centers for Disease Control and Prevention National Center for Health Statistics.
For each ED visit in NHAMCS in 2008–2013, up to three associated diagnosis codes, up to three RFV codes, and up to eight administered medications were available. We included any visit that had any ICD-9-CM/ICD-10-CM code related to drug dependence, abuse, or poisoning for cocaine use, psychostimulant use, or opioid use in any of the top three listed diagnoses codes (see Appendix 1 for complete list of ICD codes used). We excluded ICD codes that included “in remission” to capture visits related to active drug use. We adapted this approach from the Centers for Medicare and Medicaid Services and other similar studies using national data. To make groups mutually exclusive and to allow for comparisons, we excluded any visits involving two or more of the three drug-related diagnosis groups (cocaine, psychostimulant, or opioid), which were approximately 5% of unweighted eligible visits. We also excluded visits identified by NHAMCS as follow up visits and visits where the patient was seen at the same hospital within the preceding 72 hours to limit counting repeat visits for the same illness episode.

Selection of Emergency Department Visits

The sample included all ED visits made by adults (18 years or older) with the visit related to cocaine use, psychostimulant use, or opioid use, based on the International Classification of Diseases Clinical Modification (ICD-CM) visit diagnosis codes. We included any visit that had any ICD-9-CM/ICD-10-CM code related to drug dependence, abuse, or poisoning for cocaine use, psychostimulant use, or opioid use in any of the top three listed diagnoses codes (see Appendix 1 for complete list of ICD codes used). We excluded ICD codes that included “in remission” to capture visits related to active drug use. We adapted this approach from the Centers for Medicare and Medicaid Services and other similar studies using national data. To make groups mutually exclusive and to allow for comparisons, we excluded any visits involving two or more of the three drug-related diagnosis groups (cocaine, psychostimulant, or opioid), which were approximately 5% of unweighted eligible visits. We also excluded visits identified by NHAMCS as follow up visits and visits where the patient was seen at the same hospital within the preceding 72 hours to limit counting repeat visits for the same illness episode.

Measurements and Outcomes

The primary exposure of interest was the type of drug associated with the ED visit, as defined above (cocaine, psychostimulant, or opioid). The primary outcomes of interest were the chief presenting concerns, measured as dichotomous variables if visit concerns were related to: (1) psychiatric; (2) neurologic; (3) cardiopulmonary; or (4) drug toxicity/withdrawal concerns. Visits could contribute to more than one category of presenting concerns. For chief presenting concerns, NHAMCS uses an RFV coding scheme developed by NCHS, where RFV is defined as “the patient's complaint(s), symptom(s), or other reasons for this visit.” We adapted the RFV coding scheme to measure if any of the top three RFV codes associated with each visit were related to psychiatric, neurologic, cardiopulmonary, and drug toxicity/withdrawal categories of RFV codes. For example, psychiatric presenting concerns included RFV codes such as “depression” and “suicide attempt.” Cardiopulmonary concerns included codes such as “chest pain,” “shortness of breath,” and “respiratory arrest.” Drug toxicity/withdrawal concerns included “drug detoxification,” “accidental poisoning,” and “adverse effects of drug use” such as unintentional overdose (see Appendix 2 for RFV code categorization).

For each category of drug-related visits (cocaine, psychostimulant, or opioid), we described patient characteristics including age, sex, race/ethnicity, primary payer, homelessness, and multimorbidity (defined as the presence of two or more comorbidities assessed by NHAMCS). We used the imputed measure of race/ethnicity provided by NHAMCS, which adjusts for 16–18% missingness of race/ethnicity data extracted from the medical chart. We assessed hospital-level factors including urban location, US census region, and safety-net status, defined per NCHS criteria as having either > 30% of visits with the primary payer being Medicaid or uninsured, or having > 40% of visits from combined Medicaid and uninsured.

To evaluate characteristics of clinical management, we assessed diagnostic testing, administered medications, and disposition. As above, we analyzed the top eight administered medications, using the drug classification scheme developed by NCHS. We reviewed drug codes available and included any drug codes that could be classified as “atypical antipsychotics,” “benzodiazepines,” “naloxone,” or “opioids.” We additionally examined whether visits were concurrently associated with alcohol-related and other drug-related diagnoses, including cannabis, sedatives/hypnotics, etc. (Appendix 1)

Statistical analysis

We applied survey sample weights to yield an unbiased national estimate of ED visit percentages and characteristics. We calculated annual ED visit rates by dividing the weighted number of visits each year by the US Census Bureau estimates of civilian, noninstitutionalized adults aged 18 and older. We conducted a Poisson regression analysis using visit year as the ordinal predictor to test for significant trends in visits over time. We described outcomes of interest were the chief presenting concerns, measured as dichotomous variables if visit concerns were related to: (1) psychiatric; (2) neurologic; (3) cardiopulmonary; or (4) drug toxicity/withdrawal concerns. Visits could contribute to more than one category of presenting concerns. For chief presenting concerns, NHAMCS uses an RFV coding scheme developed by NCHS, where RFV is defined as “the patient's complaint(s), symptom(s), or other reasons for this visit.” We adapted the RFV coding scheme to measure if any of the top three RFV codes associated with each visit were related to psychiatric, neurologic, cardiopulmonary, and drug toxicity/withdrawal categories of RFV codes. For example, psychiatric presenting concerns included RFV codes such as “depression” and “suicide attempt.” Cardiopulmonary concerns included codes such as “chest pain,” “shortness of breath,” and “respiratory arrest.” Drug toxicity/withdrawal concerns included “drug detoxification,” “accidental poisoning,” and “adverse effects of drug use” such as unintentional overdose (see Appendix 2 for RFV code categorization).

For each category of drug-related visits (cocaine, psychostimulant, or opioid), we described patient characteristics including age, sex, race/ethnicity, primary payer, homelessness, and multimorbidity (defined as the presence of two or more comorbidities assessed by NHAMCS). We used the imputed measure of race/ethnicity provided by NHAMCS, which adjusts for 16–18% missingness of race/ethnicity data extracted from the medical chart. We assessed hospital-level factors including urban location, US census region, and safety-net status, defined per NCHS criteria as having either > 30% of visits with the primary payer being Medicaid or uninsured, or having > 40% of visits from combined Medicaid and uninsured.

To evaluate characteristics of clinical management, we assessed diagnostic testing, administered medications, and disposition. As above, we analyzed the top eight administered medications, using the drug classification scheme developed by NCHS. We reviewed drug codes available and included any drug codes that could be classified as “atypical antipsychotics,” “benzodiazepines,” “naloxone,” or “opioids.” We additionally examined whether visits were concurrently associated with alcohol-related and other drug-related diagnoses, including cannabis, sedatives/hypnotics, etc. (Appendix 1)

Statistical analysis

We applied survey sample weights to yield an unbiased national estimate of ED visit percentages and characteristics. We calculated annual ED visit rates by dividing the weighted number of visits each year by the US Census Bureau estimates of civilian, noninstitutionalized adults aged 18 and older. We conducted a Poisson regression analysis using visit year as the ordinal predictor to test for significant trends in visits over time. We described characteristics of cocaine-, psychostimulant-, and opioid-related visits using bivariate Pearson chi-squared tests. We used multivariable logistic regression to evaluate whether type of drug-related visit was associated with specific categories of chief presenting concerns, using separate models for each category. We adjusted for age, sex, race/ethnicity, and homelessness, as these factors could be associated with increased morbidity and introduce potential confounding. All reported estimates were robust, defined by NCHS as an unweighted count in each group of ≥30 visits and/or a relative standard error of ≤30%. We completed all analyses using svy routine commands within Stata/MP version 16.0 (StataCorp LLC). All p-values were two-sided and a p-value < 0.05 was used to determine statistical significance. The University of California, San Francisco Institutional Review Board exempted this study from review.

Results

Annual Rate Trends of Drug-Related Emergency Department Visits
The study sample included 1,576,000 unweighted ED visits between 2008 to 2018, which was representative of 7,121,000 weighted ED visits. The rate of cocaine-related ED visits increased from 6.6 visits per 10,000 population (95%CI 3.9–9.3) in 2008 to 8.9 visits per 10,000 population (95%CI 4.7–13.1) in 2018, though this increase was not statistically significant (p = 0.23 for test of trend). Rates of psychostimulant-related ED visits increased from 2.2 visits per 10,000 population (95%CI 0.8–3.7) to 12.9 visits per 10,000 population (95%CI 7.3–18.4) (p < 0.001). The increase in ED visits was greatest for opioids, where rates of opioid-related ED visits increased from 6.0 visits per 10,000 population (95%CI 3.7–8.2) in 2014 to 24.8 visits per 10,000 population (95%CI 18.0-31.5) in 2018 (p < 0.001) (Fig. 1).

**Characteristics of Drug-Related Emergency Department Visits**

In unadjusted analysis, psychostimulant- and opioid-related visits had comparable age and race/ethnicity distributions, whereas patients with cocaine-related visits were more likely to be among those ≥ 40 years of age and identifying as Black (p < 0.001 for both characteristics) (Table 1). Patients with cocaine- and psychostimulant-related visits were more likely to be experiencing homelessness compared to patients with opioid-related visits (cocaine 10%, psychostimulant 12%, opioid 4%; p < 0.001). Cocaine-related visits were predominantly in the South (49%), while psychostimulant-related visits were more concentrated in the West (60%), and opioid-related visits were spread out throughout all regions. Cocaine and psychostimulant-related visits were slightly more concentrated at hospitals in urban areas than opioid-related visits (cocaine 96%, psychostimulant 91%, opioid 88%; p = 0.03).
### Table 1
Demographic characteristics of national emergency department visits related to cocaine, psychostimulant, opioid use, 2008–2018

|                        | Cocaine-related visits (n = 1,406,000) | Psychostimulant-related visits (n = 1,590,000) | Opioid-related visits (n = 4,125,000) |

| **Multimorbidity**     | 19 (13, 28)                            | --                                            | 13 (10, 17)                         |

Source: National Hospital Ambulatory Medical Care Survey. Cell sizes with < 30 unweighted visits or > 30% relative standard error not included. Visits were mutually exclusive for drug type, as visits associated with two or more drug-categories were excluded. Multimorbidity as the presence of two or more comorbidities assessed by NHAMCS (including Alzheimer’s dementia, alcohol use disorder, asthma, cancer, cerebrovascular disease, chronic obstructive pulmonary disease, coronary artery disease, depression, diabetes, chronic kidney disease, end stage renal disease, venous thromboembolism, HIV/AIDS, hypertension, obesity, obstructive sleep apnea, osteoporosis, and substance use disorders).

Regarding chief presenting concerns, psychiatric concerns were more common in cocaine- and psychostimulant-related visits (cocaine 31%, psychostimulant 50%, opioid 25%; p < 0.001). Cardiopulmonary concerns were also more common in cocaine- and psychostimulant-related visits (cocaine 33%, psychostimulant 23%, opioid 12%; p < 0.001) concerns than opioid-related visits (Table 2). Drug-toxicity/withdrawal concerns were more common in opioid-related visits (cocaine 36%, psychostimulant 32%, opioid 49%; p < 0.001). Cocaine-related visits had a higher proportion of co-occurring alcohol-related diagnoses in the same ED visit (cocaine 19%, psychostimulant 6%, opioid 7%; p < 0.001).
Table 2  
Presenting concerns, clinical management, and disposition of national emergency department visits related to cocaine, psychostimulant, or opioid use, 2008–2018

| Weighted % (95% CI) | Cocaine-related visits (n = 1,406,000) | Psychostimulant-related visits (n = 1,590,000) | Opioid-related visits (n = 4,125,000) |
|-------------------|--------------------------------------|-------------------------------------------|-------------------------------------|
| **Chief presenting concern(s)** | | | |
| Psychiatric | 31 (24, 38) | 50 (42, 58) | 25 (21, 30) |
| Neurologic | 7 (4, 11) | 7 (4, 12) | 7 (4, 10) |
| Cardiopulmonary | 33 (26, 41) | 23 (17, 31) | 12 (10, 16) |
| Drug toxicity/withdrawal | 36 (30, 43) | 32 (25, 40) | 49 (43, 54) |

Source: National Hospital Ambulatory Medical Care Survey. Cell sizes with < 30 unweighted visits or > 30% relative standard error not included. Visits were mutually exclusive for drug type, as visits associated with two or more drug-categories were excluded. Chief presenting concerns defined using top three “reason for visit” codes. Visits could contribute to more than one category of chief presenting concerns.

The most common chief presenting concerns varied across groups. The most common chief presenting concern for opioid-related visits were “adverse effect of drug abuse” (27.9% of opioid-related visits), “drug detoxication” (6.0%), and “abnormal drug usage” (5.7%) (Appendix 3). The most common chief presenting concerns for cocaine-related visits were “chest pain” (27.2% of cocaine-related visits), “other problems relating to psychosis” (7.9%), and “abdominal pain” (5.7%). For psychostimulant-related visits, most common chief presenting concerns were “chest pain” (10.4% of psychostimulant-related visits), “abnormal drug usage” (9.3%), and “other symptoms related to psychosis” (8.7%).

Cocaine-related visits had the highest utilization of diagnostic testing, especially cardiovascular testing (e.g., cardiac biomarkers and monitoring). Psychostimulant-related visits had more administration of chemical restraint medications and more transfers to psychiatric facilities (cocaine 6%, psychostimulant 10%, opioid 5%; p < 0.001).

**Multivariable Analyses**
Unadjusted odd ratios (OR) showing associations between drug type and presenting concerns are shown in Table 3. Adjusting for age, sex, race/ethnicity, and homelessness, psychostimulant-related visits had greater odds of presenting with a psychiatric chief concern compared to opioid-related visits (adjusted odds ratio [aOR] 2.46, 95% CI 1.42–4.27; Table 3). No differences were seen with neurologic chief concerns. Both cocaine- and psychostimulant-related visits had greater odds of presenting with cardiopulmonary chief concerns compared to opioid-related visits (cocaine aOR 2.95, 95% CI 1.70–5.13; psychostimulant aOR 2.46, 95% CI 1.42–4.27). In contrast, psychostimulant-related visits had lower odds of presenting with drug toxicity/withdrawal concerns (aOR 0.47, 95%CI 0.30–0.73).

Discussion

In this study using nationally representative ED data, there were significant increases in opioid-related ED visits and psychostimulant-related ED visits, where the latter increased from 2.2 to 12.9 visits per 10,000 population from 2008 to 2018. This finding is consistent with other studies showing increasing national rates of ED visits, hospitalizations, and deaths from psychostimulant overdose. The increasing use of the ED and other acute care settings is likely linked to rising methamphetamine availability and use. Data from the National Forensic Laboratory Information System found methamphetamine drug case submissions increased from 2011 to 2019, with methamphetamine as the most frequently reported drug. While psychostimulant-related ED visits were predominantly among Western regions in our study, recent data highlights the emergence of psychostimulant-related overdose deaths in the Midwest and Northeast, suggesting methamphetamine is already becoming a nationwide concern. Increases in cocaine-related ED visits were not significant, potentially due to the exclusion of visits related to opioid and cocaine co-use. Polysubstance use is common in individuals using cocaine, and other studies found rates of fatal overdoses and ED visits for overdose involving cocaine and opioid use are rising.

We found stimulant-related ED visits were less likely to be identified as drug toxicity/withdrawal concerns, underscoring the differences in presentations between stimulant- and opioid-related visits. While the national surge in ED visits and deaths related to opioid overdose is linked to the rise in fentanyl in the drug supply, the main drivers of stimulant-related ED visits and overdoses are unclear. Possibilities include increased potency of fluctuating drug supplies, contamination or co-use with synthetic opioids like fentanyl, or the cumulative effects of chronic stimulant use over time. The term “overdose” may be problematic for stimulants. The “overdose” terminology commonly referring to an acute respiratory event from an episode of opioid use may be problematic when applied to stimulants, as it lacks specificity in capturing the diverse ways in which stimulant toxicity can present. Because of this variety in stimulant-related presentations, acute complications from stimulant use are more likely to comprise a toxidrome of multiple potential symptoms. Addressing acute stimulant toxicity may rely more on clinical management of various symptoms, rather than the development of a single reversal agent like naloxone for opioid overdose.

The ED has become a critical setting in responding to the opioid overdose crisis and addressing the health needs of people who use drugs, particularly among low-income and uninsured populations. EDs have taken up campaigns to distribute naloxone, initiate buprenorphine prescriptions for opioid use disorder treatment, and develop referral programs to increase linkages to treatment services. Similarly, the ED can become a point of intervention for addressing acute and chronic complications of stimulant use disorders. While no current medications are approved by the Food and Drug Administration, several medications show early promise. Behavioral treatments such as contingency management and cognitive behavioral...
therapy are effective in reducing stimulant use, though few are able to access these treatment modalities, especially for publicly insured populations where reimbursement is limited.55–57 EDs facing a high burden of stimulant-related visits could implement a navigator to facilitate linkages to existing stimulant use treatment programs, similar to what has been done for other substance use disorders,49,58 or offer harm reduction kits to reduce preventable complications of drug use. As methamphetamine-related ED visits are associated with longer length of stays and higher costs,14 facilitating linkages to stimulant use treatment from the ED could help reduce acute care costs and would align with national policies focused on expanding access to treatment.59

Cocaine-related ED visits were predominately made by individuals who were older, male, and Black. Potential reasons include differences in drug supply, disparities in comorbidities, socioeconomic disadvantage, and other factors related to structural racism that can affect health and healthcare access.50,61 Complications from cocaine use are disproportionately higher in Black communities, where rates of cocaine-related deaths are comparable to the rates of opioid-related deaths in white individuals.60 Yet cocaine-related harms have largely been understudied in recent years, and this is alarming given overdose death rates in Black individuals are rising faster compared to whites.62,63 As the country begins to address the rising epidemic of stimulant-related deaths, interventions addressing stimulant use must address racial equity and pay attention to both cocaine and psychostimulant use to avoid further exacerbating existing racial and economic structural disparities.54

Both cocaine- and psychostimulant-related ED visits were associated with cardiopulmonary concerns, even after adjusting for factors associated with increased cardiovascular risk. Both cocaine and psychostimulants are known cardiotoxins, and both acute and chronic use can lead to adverse events such as myocardial ischemia, stroke, and heart failure.17,65,66 Patients using stimulants who develop chronic cardiovascular conditions such as heart failure, despite being younger, face more severe in-hospital complications with higher rates of readmission compared to patients with non-stimulant-related heart failure.67,68 These findings suggest a need for targeted cardiopulmonary interventions for people who present to the ED with stimulant-related diagnoses.

We found psychostimulant-related ED visits were strongly associated with psychiatric concerns, had greater administration of chemical restraint medications, and had more transfers to psychiatric facilities. Single center ED studies have drawn similar conclusions,14,15 and our study using national data adds generalizability to these findings. Use of methamphetamine not only precipitates psychotic symptoms, but methamphetamine use also exacerbates underlying psychiatric illness.14,69 Paired with high rates of homelessness seen in patients with stimulant-related ED visits, these findings are especially relevant for urban areas where addressing acute psychiatric presentations and homelessness are pressing concerns.

Several limitations should be considered. We excluded visits that included diagnoses related to both opioid and stimulant use, which may underestimate both the rates of drug-related ED visits and the role of polysubstance use. Prior work has shown combined opioid and stimulant overdose deaths often present similar to opioid-only overdose deaths,33 and this may apply as well be true for ED visits related to both opioid and stimulant use. The transition from ICD-9-CM to ICD-10-CM codes starting in 2015 potentially affected trends, as increasing rates of drug-related visits during this period could be attributed to this transition.34 However, the continued rise across all drug-related ED visits after 2015 provides reassurance that our trends have validity. Diagnostic coding of visits may not have accurately captured all-drug related ED visits, as it often relies on the judgment of the treating physician which may introduce misclassification. Though this preliminary data is needed to set the stage for longitudinal prospective studies to validate these findings. Finally, we could not distinguish between visits related to methamphetamine versus other psychostimulants, as there are no methamphetamine-specific ICD codes. Previous studies have shown that psychostimulant-related ICD codes have high positive predictive values for methamphetamine use, particularly in acute care settings.2,6,7,35

Conclusions

Psychostimulant-related ED visits increased substantially from 2008 to 2018. Cocaine- and psychostimulant-related ED visits differ in presentation and management from opioid-related ED visits. They are less often identified as related to drug toxicity/withdrawal and require more interventions to address cardiopulmonary and psychiatric complications.

Declarations

Ethics approval: As the study uses publicly available datasets, the University of California San Francisco Institutional Review Board exempted this study from review.

Consent for Publication: Not applicable.

Availability of data and materials: All data is made publicly available through the National Center of Health Statistics and can be accessed through their website at https://www.cdc.gov/nchs/ahcd/index.htm
Prior presentations: None.

Potential Competing Interest(s): KTL has received research funding unrelated to this work from the California Department of Health Care Services, Public Health Institute, Sierra Health Foundation, and Substance Abuse and Mental Health Services Administration. POC serves on the Board of Scientific Counselors, National Center for Injury Prevention and Control, Centers for Disease Control and Prevention.

Funding: LWS was supported by the UCSF National Clinical Scholars Program and the San Francisco Veteran Affairs Medical Center. TDM has received training support from the National Institute on Drug Abuse (T32 DA007250). POC was supported by the National Institute on Drug Abuse (K24DA042720). The funding agencies had no role in study design, data collection, analysis, the decision to publish, or the preparation of the manuscript.

Author contributions: LWS and PC conceived the study and designed the study. LWS analyzed the data. TDM provided statistical advice on data analysis. All authors contributed to data interpretation. LWS and PC drafted the article, and all authors contributed substantially to its revision.

Acknowledgements: We thank Christopher Cairns and Loredana Santo at the Division of Health Care Statistics at the National Center for Health Statistics, and Dr. John Neuhaus at the UCSF Epidemiology & Biostatistics, for their assistance with the data. We would also like to thank the UCSF National Clinical Scholars Program for their support of this work.

Figures
Figure 1

Annual trends in rates of national emergency department visits related to cocaine, psychostimulant, or opioid use, 2008-2018. Emergency department visits categorized by drug-type if any of the top three ICD9-CM/ICD10-CM diagnoses codes were related to opioid, cocaine, or psychostimulant use. Visits were mutually exclusive for drug type, as visits associated with two or more drug-categories were excluded. Rates were calculated by dividing weighted number of visits in each year by US Census Bureau estimates of civilian, noninstitutionalized adults aged 18 and older for that year. All rates per 10,000 population. Source: National Hospital Ambulatory Medical Care Survey.
