Air Oxidized Activated Carbon Catalyst for Aerobic Oxidative Aromatizations of N-Heterocycles

Lukas Enders, David S. Casadio, Santeri Aikonen, Anna Lenarda, Tom Wirtanen, Tao Hu, Sami Hietala, Lucilia S. Ribeiro, Manuel Fernando R. Pereira and Juho Helaja*

Abstract A simple “reagent-free” thermal air treatment turns active carbon into a mildly oxidized material with an increased quinoidic content that catalytically dehydrogenates saturated N-heterocycles to the corresponding aromatic compounds. Additional thermal decarboxylation improves the activity of the catalyst further, making it overall more efficient compared to other widely used carbocatalysts such as oxidized carbon nanotubes, graphene oxide and untreated active carbons. The substrate scope covers 1,2,3,4-tetrahydroquinolines (THQ), 1,2,3,4-tetrahydro-β-carbolines and related N-heterocyclic structures. The developed protocol also successfully dehydrogenates 3-(cyclohexenyl)indoles to 3-aryl indoles, which opens a concise transition metal-free approach to (hetero)biaryls as exemplified with the synthesis of the core structure of progesterone receptor antagonist. Hammett plots, deuterium KIE measurements and computations at DFT level suggest that bimolecular hydride transfer mechanism is more likely to operate between THQs and o-quinoidic sites of the catalyst, than the addition-elimination hemiaminal route. Comparison of structural parameters and catalytic performance of various oxidized carbon materials, prepared by different oxidative and optional post treatments, revealed that quinoidic content and surface area correlates with the obtained yields, while carboxylic acid contents have a clear inhibiting effect for the studied oxidative dehydrogenations (ODHs). The carbocatalyst itself can be prepared from inexpensive and environmentally benign starting materials and its catalytic activity can be enhanced by a simple thermal oxidation in air that produces no reagent waste. Furthermore, oxygen is used as terminal oxidant, and the carbocatalyst is recyclable for at least six times without a notable loss of activity.

Introduction
Activated carbons (ACs) are highly versatile materials with a wide range of applications from medicinal use to water purification and catalytic processes.1 Among ACs’ many interesting properties, high surface area and extensive porosity are the epicenter of their success in these fields. In catalysis, ACs have traditionally been used as supports for transition metal composites or nanoparticles but also, in growing numbers, as catalysts on their own merit.2 As a matter of fact, carbocatalysis has been known for almost over a century, but the growing demand for greener catalytic processes has fueled its further development in the last decades.3–5

From sustainable chemistry perspective, carbocatalysis is becoming an increasingly interesting concept: heterogeneous materials derived from abundant second row elements can promote reactions that are usually either performed with stoichiometric reagents or catalysed by transition metals. As a result, both reagent waste and demand for critical metals are reduced – both key aspects in green chemistry. Moreover, in oxidations, when (atmospheric) oxygen is employed to regenerate carbocatalyst’s active sites, water and/or hydrogen peroxide is the only by-products generated.6,7

Alongside ACs,8–12 other carbon allotropes such as carbon nanotubes (CNTs),11–15 nanodiamonds (NDs), graphene oxides (GOs),16–18 and nanohorns, have been employed as catalysts (Scheme 1) for organic transformations.19,20 Gas-phase dehydrogenations of hydrocarbons in particular have been extensively studied with these materials, with received yields comparable to those of AC.21 In gas-phase the oxidative catalysis at high temperatures causes combustion and “coking” of ACs and justifies the use of more resistant carbon nanomaterials.22 However, in a liquid-phase at low temperatures the degradation of AC is not an issue in oxidative carbocatalysis, which makes ACs highly appealing over the other allotropes (Scheme 1).
Results and discussion

We began our study by screening several carbon materials as catalysts for the ODH aromatization of 1-tert-butyl-1,2,3,4-tetrahydro-β-carboline (1a) to the corresponding β-carboline (2a) in toluene over 24 h at 90 °C under O2-atmosphere (Table 1). The use of HCl washed commercial active carbon (AC-dm) delivered 2a in 34% yield (entry 1). Surprisingly, yield increased only by 2% when HNO3-oxidized active carbon (oAC-HNO3) was used as catalyst, as in previous studies we found this catalyst to be highly suitable for the homocoupling of heteroaryls (entry 2). Similarly, 57% of 2a was received when AC-dm was oxidized thermally under static air (oAC-air, entry 3). We then subjected this material to a thermal post-treatment under Ar at 425 °C, which is known to remove carboxylates selectively. The obtained material (oAC-air(Δ) gave a slightly better yield of 59% (entry 4). The reaction conditions were optimized using a rather high, 896 mg · mmol⁻¹ catalyst loading, equal to four weight equiv of 1a, which was the utmost limit that allowed efficient stirring of the reaction suspension (0.25 M) using 24 h reaction time. Furthermore, widely used carbonaceous catalyst GO and its reduced form rGO delivered yields of 1% and 52%, respectively (entries 5 and 6). Previously, we have reported rather good results for ODH C-C couplings of aryls with HNO3-oxidized carbon nanotubes (oCNT, entry 7), but for the current reaction, this catalyst delivered only 20% yield.

Table 1. Screening of carbocatalysts and model compounds

| Entry | Catalyst* | Yield (%) |
|-------|-----------|-----------|
| 1     | AC-dm     | 34        |
| 2     | oAC-HNO3  | 36        |
| 3     | AC-dm (air oxidized AC-dm) | 425 °C | 57 |
| 4     | oAC-air(Δ) (air oxidized, decarboxylated*) | 59 |
| 5     | GO        | 1         |
| 6     | rGO       | 52        |
| 7     | oCNT      | 20        |

Model compounds for carbon material:

| Entry | Compound          | Yield (%) |

| 8     | 1a                | 2         |
| 9     | Tetracene (0.5 equiv) | 1         |
| 10    | Anthraquinone (0.5 equiv) | 2         |
| 11    | Phenanthrenequinone (0.5 equiv) | 33 (22) f |

* Catalyst loading = 896 mg · mmol⁻¹ of SM (0.25 M). a as determined by 1H NMR spectroscopy using 1,3,5-trimethoxybenzene as an internal standard. b weight equiv, Few Layer modified Hummer’s (Cheaptubes.com). c ref 15, d by thermal treatment under Ar for 24 h at 450 °C (Si), e Under Ar (24 h).

ACs are, in fact, commercially available in many forms and much cheaper than the other carbon (nano)materials. In addition, they are available as a high volume bulk product and they can be prepared from non-fossil feedstock (e.g., lignin, cellulose, agricultural waste). Furthermore, their catalytic activity can be enhanced by a simple, safe and ecological treatment. Graphene oxide from graphite usually requires highly corrosive and toxic process waste. In contrast, the preparation of graphene oxide (GO) and reduced graphene oxide (rGO) delivered yields of 1% and 52%, respectively (entries 5 and 6). Previously, we have reported that the use of graphene oxide (GO) as catalyst, as in previous studies we found this catalyst to be highly suitable for the homocoupling of heteroaryls (entry 2). Similarly, 57% of 2a was received when AC-dm was oxidized thermally under static air (oAC-air, entry 3). We then subjected this material to a thermal post-treatment under Ar at 425 °C, which is known to remove carboxylates selectively. The obtained material (oAC-air(Δ) gave a slightly better yield of 59% (entry 4). The reaction conditions were optimized using a rather high, 896 mg · mmol⁻¹ catalyst loading, equal to four weight equiv of 1a, which was the utmost limit that allowed efficient stirring of the reaction suspension (0.25 M) using 24 h reaction time. Furthermore, widely used carbonaceous catalyst GO and its reduced form rGO delivered yields of 1% and 52%, respectively (entries 5 and 6). Previously, we have reported rather good results for ODH C-C couplings of aryls with HNO3-oxidized carbon nanotubes (oCNT, entry 7), but for the current reaction, this catalyst delivered only 20% yield.

Table 1. Screening of carbocatalysts and model compounds

| Entry | Catalyst* | Yield (%) |
|-------|-----------|-----------|
| 1     | AC-dm     | 34        |
| 2     | oAC-HNO3  | 36        |
| 3     | AC-dm (air oxidized AC-dm) | 425 °C | 57 |
| 4     | oAC-air(Δ) (air oxidized, decarboxylated*) | 59 |
| 5     | GO        | 1         |

| 10    | Anthraquinone (0.5 equiv) | 2         |
| 11    | Phenanthrenequinone (0.5 equiv) | 33 (22) f |

* Catalyst loading = 896 mg · mmol⁻¹ of SM (0.25 M). a as determined by 1H NMR spectroscopy using 1,3,5-trimethoxybenzene as an internal standard. b weight equiv, Few Layer modified Hummer’s (Cheaptubes.com). c ref 15, d by thermal treatment under Ar for 24 h at 450 °C (Si), e Under Ar (24 h).

Next, we performed reference tests to identify the possible active sites of the carbocatalyst. In absence of any catalyst, we
received only 2% of 2a (entry 8). We then employed different model conditions which were been used before to mimic the active sites in carbocatalysts.\textsuperscript{39,40} Tetracene and anthraquinone delivered only marginal yields of 1% and 2% (entries 9-10). Remarkably, phenanthrenequinone produced 33% and 22% of 2a under O\textsubscript{2} and Ar atmospheres, respectively (entry 11). All the results suggest that the quinoidic groups function as the actives sites of the catalyst, which is in accordance with the characterization of the material (vide infra) and the literature.\textsuperscript{2,11,20}

To expose the critical reaction parameters, the standard conditions were varied (Table 2). Decreasing the catalyst loading to one and two equivalents also decreased the yields to 30% and 42%, respectively (entries 2,3). Interestingly, increasing the reaction time to 72 h increased the yield to 67%, while decreasing the time to 3 h resulted in 44% yield (entries 4 and 5). Drastic differences were also observed upon changing the temperature. At room temperature, the reaction proceeded poorly with a low yield of 26% (entry 6), while in contrast we obtained 2a in 67% yield when we raised the temperature to 140 °C (entry 7). We performed the latter experiment in anisole, which in addition to its higher boiling point, also has complementary value both in terms of safety and environmental profile.\textsuperscript{41,42} Based on literature,\textsuperscript{6,8,11} we supposed that molecular oxygen was acting as the terminal oxidant, so we investigated its role by running the reaction under inert atmosphere (Table 2, entry 8). Surprisingly, we obtained 24% yield, despite thorough removal of oxygen from the reaction mixture. This modest activity suggests a possible stoichiometric interaction under Ar atmosphere with the presumed quinoidic active sites (vide infra). An addition of MsOH (entry 9), which was previously crucial for the carbocatalysed coupling of benzo fused heterocycles,\textsuperscript{12} decreased the yield drastically to 22%. In the absence of carbocatalyst, only 2% yield was received (entry 10).

Table 2. Variation of the reaction conditions in the aromatization of tetrahydro-\(\beta\)-carboline 1a ODH

| Entry | Variation from the standard conditions \(^{a}\) | Yield (%) |

\(^{a}\) 896 mg - mmol\(^{-1}\) of SM (0.25 M);

With the optimized conditions at hand, we studied the scope of ODH aromatization with 1,2,3,4-tetrahydro-\(\beta\)-carbolines, 1,2,3,4-tetrahydroquinolines and related tetrahydroaryl N-heterocyclic structures (Scheme 2). Due to the observed difference in reactivity between oAC\(_{\text{HDO}}\) and oAC\(_{\text{HDO}}(\text{TH})\) during the synthesis of 1-tert-butyl-\(\beta\)-carboline (2a, Table 1), we screened the dehydrogenation of various tetrahydro N-heterocycles with the both catalysts. The complete list is presented in Table S1 (SI), but for the most of the substrates oAC\(_{\text{HDO}}(\text{TH})\) was more active (Scheme 2).

We first explored the preparation of \(\beta\)-carboline substructures within the well-known harmala alkaloid family (Table 3, entries 1-5), as well as 6-methoxy-\(\beta\)-carboline. We observed that upon addition of a methoxy substituent at C6 and removal of fBu from C1, the yield dropped from 59% (2a) to 38% (6-methoxy-\(\beta\)-carboline, 2b). The yield was lowered even more drastically for harmine 2c (12%) and iso harmine 2d (7%). Additionally, for the substrates 1a–1d the dihydro-imine intermediates could be isolated (see SI). On the other hand, 1-phenyl-substituted substrate 1x exhibited higher reactivity, and was converted with 75% yield to 2x in 24 h (86% yield in 72 h). We then moved to study various quinoline-derivatives. All 6-substituted 1,2,3,4-tetrahydroquinolines (THQs) were dehydrogenated in excellent to quantitative yields. Notable exceptions were 6-bromo and 6-chloro derivatives that were obtained in 66% and 72% yields, respectively (Table 3, entry 6).

Quinoxaline (2o) was dehydrogenated from its 1,2,3,4-tetrahydro precursor in 67% yield and 1,2,3,4-tetrahydroisoquinoline (1q, THIQ) was converted to isoquinoline in 40% yield. The yield of isoquinoline could be further improved to 67% by extending the reaction time to 72 h and raising the temperature from 90 °C to 100 °C. Slightly better yields were received with oAC\(_{\text{HNO}}\) (56 % and 55 %) than with oAC\(_{\text{HDO}}(\text{TH})\) (53 % and 47 %) for quinaldine (2m) and 2,6-dihydroxyquinoline (2n), respectively.

To prove the catalytic nature of the carbon material, we performed an additional test with 1-phenyl-1,2,3,4-tetrahydro-\(\beta\)-carboline (1x) ODH to 2x. At the first stage, the reaction was run for 24 h under argon at otherwise standard conditions (Table 2). Thereafter, at the second phase, the atmosphere was exchanged to O\textsubscript{2} and the reaction was stirred for an additional 24 h. After the first step, the reaction delivered only 35% yield, however, when the second stage was completed, 71% of 2x was received. The test proves that the oxygen reactivates the consumed catalyst, reinitiating the catalytic cycle.
Initially, when the optimized conditions for the previous ODH indoles to the corresponding 2,3-diphenylindole derivatives were used, we could only obtain products in low yields. However, when we changed the solvent to anisole and raised the temperature to 140 °C we obtained 1H-2,3-diphenylindole in 61% yield. The scope of the reaction was explored using 2-phenyl-indole as the backbone structure and varying the 3-tetrahydroaryl substituent. Overall, the yields for most 3-aryl-2-phenyl-indoles were moderate, varying between 49–72% with 24–72 h reaction time. Interestingly, 3-(4-methoxy-tetrahydroaryl)-2-phenyl-indole (3d) yielded mainly the elimination product 2,3-diphenyl-indole (4a). Interestingly, a control test in the absence of carboxylate yielded only 4% of 3b after 72 h reaction time.

As 3-tetrahydroaryl indoles can be straightforwardly prepared via a condensation reaction between indoles and the cyclohexanones (see SI), the developed methodology does not only open a concise synthetic route, but also a transition metal-free access to biaryl compounds that are typically prepared with Pd-mediated couplings (in this case by Suzuki-Miyaura couplings) from halide and boronic acid (or ester) functionalized aryls. Importantly, the developed method allows the employment of unprotected (NH)-indoles as substrates that are often not tolerated in Pd-coupling reactions. The development of this protocol is of significant synthetic relevance as many 3-aryl indoles are core structures of active pharmaceutical ingredients of marketed drugs.

Next, we became curious whether we could extend the ODH method to the aromatization of 2-phenyl-3-(cyclohexenyl)-indoles to the corresponding 2,3-diphenylindole derivatives. Initially, when the optimized conditions for the previous ODH aromatizations were used, we could only obtain products in low yields. However, when we changed the solvent to anisole and raised the temperature to 140 °C we obtained 1H-2,3-diphenylindole in 61% yield. The scope of the reaction was explored using 2-phenyl-indole as the backbone structure and varying the 3-tetrahydroaryl substituent (Table 4). Overall, the yields for most 3-aryl-2-phenyl-indoles were moderate, varying between 49–72% with 24–72 h reaction time. Interestingly, 3-(4-methoxy-tetrahydroaryl)-2-phenyl-indole (3d) yielded mainly the elimination product 2,3-diphenyl-indole (4a). Interestingly, a control test in the absence of carboxylate yielded only 4% of 3b after 72 h reaction time.

---

As 3-tetrahydroaryl indoles can be straightforwardly prepared via a condensation reaction between indoles and the cyclohexanones (see SI), the developed methodology does not only open a concise synthetic route, but also a transition metal-free access to biaryl compounds that are typically prepared with Pd-mediated couplings (in this case by Suzuki-Miyaura couplings) from halide and boronic acid (or ester) functionalized aryls. Importantly, the developed method allows the employment of unprotected (NH)-indoles as substrates that are often not tolerated in Pd-coupling reactions. The development of this protocol is of significant synthetic relevance as many 3-aryl indoles are core structures of active pharmaceutical ingredients of marketed drugs.

In order to test the viability of the concept, we synthesized 3-aryl indole 7 that is the core structure of the progesterone receptor antagonists (Scheme 2). The synthesis was carried out in only
two steps with 41% yield without prefunctionalization or N-protection, while the reported Pd-coupling protocols required halogen functionalization at the indole C3 position and 4–6 steps to deliver the product or other 3-aryl indole analogues.45

Scheme 2. One pot synthesis of progesterone receptor antagonist related 3-aryl indole 7.

Fig. 1  a) Kinetic 1H NMR monitoring of 1a conversion to 2a via 1a’ (3,4-dihydrocarbazole) intermediate catalysed by oACair(Δ) (red curve) and oACmin (black curve) at 90 °C (working up the reaction at each time point), b) Catalysts recyclability test over 6 cycles in toluene with oACair(Δ) (black bars) and oAC (red bars) for 24 h under O2(Δ) for 24 h under O2(Δ) and OAO(Δ) for 24 h under O2(Δ) and OAO(Δ) at 90°C. After each run, the catalyst was filtered off and washed thoroughly with CH2Cl2/MeOH (93/7). The yield was determined by 1H-NMR using 1,3,5-trimethoxybenzene as an internal standard.

Kinetic monitoring of 1a with 1H NMR, performed with both oACmin and oACair(Δ) catalysts, indicates that the dehydrogenation reaction to 2a proceeds via 3,4-dihydro intermediate (Fig. 1a). The reaction monitoring also quantifies the better catalytic activity of the air oxidized catalyst compared to the HNO3 oxidized one (Fig. 1b). Based on our previous oAC studies,12 and reference compound stoichiometric experiments (see phenanthrenequinone in Table 1), we presume that the quinoidic groups are the active sites in oAC catalysts. To support this hypothesis, we analysed the employed carbocatalysts with X-ray photoelectron spectroscopy (XPS) to evaluate their surface properties (see SI). From the survey spectra it was possible to determine the O% of each sample, and evaluate the efficacy of each catalyst preparation protocol in introducing O-containing groups (Table S2 and S3). When compared to ACair, (Fig. 2a), oACmin exhibits a higher amount of C=O groups, as well as abundant C-OH and O-C=O groups, while the oxidation occurs with concurrent deterioration of the graphitic surface C(sp2, π-π*). In contrast, the thermal air-oxidation (oACair) is gentler for the π-surface, but also produces less oxygen containing functional groups. Raman measurements (SI) support this assumption, as higher I0/Ig ratio was calculated for oACmin (1.02) than for oACair(Δ) (0.97), indicating increased defectivity and reduction of graphene-type domains in the HNO3-oxidized carbon.

The thermal decarboxylative post-treatment under N2 notably increases the relative C=O content in the oACair(Δ) material. Based on combined material characterization, the nitric acid treatment is more efficient in promoting the formation of oxygen functionalities. However, the O1s peak deconvolution (Table 5) reveals that there is a significant difference in acidic group abundance between oACmin and oACair(Δ). This seems to be critical for the catalytic activity towards the explored reactions. Similar poor reactivity was also demonstrated for GO (Table 1), where the high degree of oxidation and abundance of −COOH groups are both characteristic features.46 The oxygen containing functional group content was also examined with temperature-programmed desorption (TPD). The CO2 desorption curve (Fig. 2c) highlights the divergent abundance of carboxylic acid groups in the two different materials; absence in oACair(Δ) and high distribution in oACmin, confirming the XPS results. From the CO desorption curves (Fig. 2d), it is noticeable how both materials are rich in carboxyls, although oACair(Δ) displays an additional shoulder at higher temperature (>800 °C) that can be associated with quinones and basic functionalities such as chromenes and pyrones (deconvolution of the TPD curves are presented in SI). This feature was confirmed by MAS NMR (Fig. 2b): the broad peak appearing around 190-200 ppm in oACair(Δ) spectrum is further evidence of higher abundance of quinones.

Textural properties were analyzed with N2 physisorption (Fig. S26). Both catalysts present adsorption isotherms of the type I plus II that implies the presence of micro and mesopores within the materials. The hysteresis loops of type H4 are associated with a narrow slit-like mesopores. The BET surface area appears to slightly decrease with the nitric acid treatment, while it increases in the case of air oxidation (Table S8). The increased available surface can be recognized as another feature contributing to the better catalytic performance of oACair(Δ).
Next, we analyzed the combined effect of high surface area and carbonyl content on the catalyst activity for the dehydrogenation of both 1-tert-butyl-1,2,3,4-tetrahydro-β-carboline (1a) and 1,2,3,4-tetrahydroquinoline (1e) (Fig. 3). For both reactions, a direct correlation between these parameters can be noticed: the highest yields are obtained when there is a combination of high surface area and high carbonyl content. One exception to this trend is oAC_{HNO3}, which stands out due to its lower catalytic activity, despite having the highest C=O % and high surface area. The moderate obtained yields can be ascribed to its high carboxylic acid content, which appears to inhibit the studied reactions. To gain further proof of this, oCNTs and oAC_{HNO3} were subjected to the same decarboxylation treatment as oAC_{air(Δ)} (450 °C for 24 h under Ar atmosphere), which caused only minor changes in the materials’ carbonyl content and surface area (see Fig. 3 and SI). These decarboxylated materials delivered remarkably increased yields for both reactions, proving that the high acid content has a detrimental effect for the studied ODH carbocatalysis.

Finally, the recyclability of the catalysts was tested to determine their robustness, as well as their catalytic nature. For this purpose, both oAC_{HNO3} and oAC_{air(Δ)} were used for six sequential cycles of 1-tert-butyl-1,2,3,4-tetrahydro-β-carboline (1a) dehydrogenation. Between the cycles, the carbocatalysts were filtered off and thoroughly washed with CH₂Cl₂/MeOH (93/7%). As shown in Fig. 1b, no major decrease in catalytic activity was observed, indicating robustness of both carbocatalysts. Therefore, we can state that the carbon materials act mainly as catalysts, only marginally taking part in the reaction in a stoichiometric way. This contrasts the recent report that casts some doubts over the catalytic nature of GO in (alcohol) oxidation reactions.⁴⁷ To further enforce our statement, the two carbocatalysts were analysed by XPS after the recycling experiments and the oxygen peaks were compared to the ones measured before the catalysis (Table 5). As summarized in Table 5, the changes in the oxygen groups’ distribution is almost negligible in the both cases. Noticeably, a peak associated to pyrrolic Ns appears after the recycling, which can indicate a possible partial stoichiometric reactivity between the carbon and the substrate.
Inductively coupled plasma mass spectrometry (ICP-MS) was used to investigate the possible presence of residual metal impurities. The study revealed that the carbon materials examined contain a maximum of 600 ppm of Fe and notably lower amounts of other metal impurities (e.g., Ni < 30 ppm, Mn = 40 ppm, Cu = 20 ppm, Co < 3 ppm and Pd < 0.2 ppm; Table S4), which makes trace metal impurity catalysis unlikely. The high carbon material loadings used in the catalytic runs may raise questions about the actual catalytic nature of oACs. TPD analysis of oACs shows that the total concentration of carbonyls and quinones is 1861 μmol/g, which makes the loading for each catalytic cycle appear quite high (416 μmol for 250 μmol of starting material). Anyhow, this theoretical maximum of catalytically active quinone sites is calculated presuming that all the carbonyls are in quinone-type configurations and that they are accessible by the substrates, which is questionable, as ACs have high microporous surface areas (see BET analysis Fig. S32). The model compound studies strongly suggests that only some quinone configurations are active in the catalytic process. Considering that TPD analysis does not discriminate the different configurations of quinones and carbonyls, we can assume that the actual number of redox active sites for each run is considerably lower. This consideration, together with the good recyclability of the carbocatalyst shines a light on the reason why such high catalyst loading is required, mitigating the doubts on the actual catalytic nature of the material.

We then turned our attention to the reaction mechanism of the oxidative carbocatalyzed aromatizations. We chose THQs as mechanistic probes as they were the most reactive substrates, and different 6-R-THQs (see Scheme 2) can be easily prepared or they are commercially available.

Quinoidic groups have been pinpointed by various studies as the mediators of carbon catalysed dehydrogenations in both gas and liquid phase. Furthermore, they have been also identified as active sites in ODH C-C couplings of various (hetero)aryl substrates. Usually, hydrogen abstraction is proposed as a reasonable mechanistic route in the gas-phase dehydrogenative reactions. However, in the liquid phase more mechanistic pathways become possible and the dehydrogenation does not necessarily need to proceed via neutral radical intermediates. The commonly proposed reaction mechanisms in homogeneous quinone-promoted oxidations include sequential electron-proton transfer, hydrogen atom transfer, and hydride transfer. In addition, Stahl and coworkers have reasoned that the oxidation of THIQ with phenanthroline could take place via a hemiaminal pathway. Building on these mechanistic proposals for both heterogeneous and homogeneous quinones, we consider the following alternatives: i) H-abstraction, ii) bimolecular hydride transfer, and iii) hemiaminal pathway.

Firstly, we performed the reaction in the presence of 1 equiv of radical scavenger 2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPO). Interestingly, TEMPO did not trap any radicals and neither had any influence on the received yields.

We then performed a Hammett plot study by varying the substituent at THQ’s 6-position (Fig. 4). The observed negative ρ-value (~0.45 or ~0.43, see Fig. 3a) suggested the formation of a positive charge in the transition state of the rate-limiting step. Linear fitting without the halogen substituted substrates shows excellent correlation in Fig. 4a ($R^2 = 0.999$) between the $\sigma_{\text{para}}$ values and $\log k/k_0$. The divergent results with the halogenated THQs can arise from the resonance effects not captured by the Hammett $\sigma_{\text{para}}$ values.

**Table 5. Summary of O1s XPS peak deconvolutions for oAC before and after, and oAC recycled before and after the recycling. (The values are in %)**

| Material                  | H2O | O-C=O | C-O esters, anhydrides | C-OH | C=O | N (pyrrolic) |
|---------------------------|-----|-------|-------------------------|------|-----|--------------|
| oAC before                | 0.39 | 2.29  | 4.79                    | 4.51 | 2.21|
| oAC recycled              | 0.34 | 2.09  | 3.27                    | 3.91 | 2.53| 3.19         |
| oAC before                | 0.73 | 0.93  | 3.04                    | 1.95 | 1.69|
| oAC recycled              | 0.35 | 1.37  | 3.12                    | 2.23 | 1.85| 1.78         |
We then decided to compute the activation free energies for the dehydrogenation reaction for both hydride transfer and hemiaminal pathway mechanisms. We selected phenanthrenequinone (PQ) and ortho-benzoquinone (o-BQ) as the model quinoidic fragments\cite{15} and 1e as the model substrate. The computed activation free energy barriers indicate that the rate-determining steps for both mechanisms – hydride transfer (TS1) and hemiaminal pathway (TS5) – are energetically close (see Fig. 5 and SI): $\Delta G^\ddagger$(TS1$_{o-BQ}$) = 27.1 kcal/mol versus $\Delta G^\ddagger$(TS5$_{o-BQ}$) = 28.5 kcal/mol and $\Delta G^\ddagger$(TS1$_{p-BQ}$) = 31.3 kcal/mol versus $\Delta G^\ddagger$(TS5$_{p-BQ}$) = 35.4 kcal/mol. Therefore, the mechanisms can coexist, see SI for details. The activation free energy barriers are, however, dependent on the properties of the model quinone, i.e., reduction potential, electrophilicity and hydride affinity, and thus accurate prediction of the activation free energies is not possible without accurate models of the carbon material.

Experimental
Preparation of Carbocatalysts

Preparation of AC_{dm} (removal of metal impurities): 16.0 g of AC (1 kg batch (Lot. H2430) from Fluka with 100 mesh particle size) were placed in a flask and 130 mL of 1 M HCl (aq.) were added. After stirring for 6 h at 70 °C, AC was filtered off and washed with 3 L of dist. H2O. AC_{dm} was dried in an oven at 140 °C for 16 h and was obtained in a yield of 16.0 g.

Preparation of oAC_{NO3}: AC_{dm} (4.00 g) was placed in a flask and 8 mL of nitric acid (68 % aq.) was slowly added forming a slurry. The flask was attached to a Dreschel bottle with NaOH aq., and then the flask was heated to 140 °C for 15 h. oAC was then dried in vacuum at 140 °C for 2 h, resulting in a yield of oAC_{NO3} of 3.88 g.

Preparation of oAC_{air}: AC_{dm} (4.00 g) was placed in a porcelain crucible which was heated to 425 °C for 16 h (30 °C · min⁻¹) in an oven in presence of air. oAC_{air} was obtained in a yield of 3.11 g.

Preparation of oAC_{Ar} (RT): oAC_{air} (3.11 g) was placed in a tubular oven under Ar flow (40 cm³ · min⁻¹) for 23 h. The temperature was increased from RT to 450 °C (10 °C · min⁻¹) and kept at 450 °C for 24 h while maintaining the Ar flow. After cooling to RT, oAC_{Ar} (RT) was obtained in a yield of 3.05 g.

General Procedure for Carbocatalytic Oxidative Dehydrogenations
Carbocatalyst and starting material were placed in a vial and the appropriate solvent was added. The vial was sealed with a cap with septum. The vial was evacuated and filled with the appropriate gas in 3 cycles and the reaction was stirred at an appropriate temperature. The carbocatalyst was then removed by filtration of the reaction mixture over a column of Celite, and was followed by washed with DCM/MeOH to obtain the products.

Conclusions
We have developed oxidized active carbon-based catalysts for the dehydrogenation of aryl fused N-heterocycles and 3-(cyclohexenyl)-indoles. The metal-free carbon materials operate in a catalytic fashion using O₂ as the terminal oxidant. With respect to the heterogeneous dehydrogenation, the developed oAC material offers improved efficiency compared to reported ACs and other reported carbon allotropes like GO and CNTs. Regarding 3-(cyclohexenyl)-indoles, we were able to demonstrate an alternative route for (hetero)biaryls that were previously obtained with multistep transition metal-mediated sequence. This opens a novel path for the synthesis of a family of indole-based medical compounds, traditionally relying on highly toxic chemicals as well as transition metal catalysis. The catalytic behaviour and robustness of the oACs was confirmed by recyclability tests, which showed remarkable stability over six cycles. While carbocatalyst development studies typically focus on determining the active sites and increasing their abundance, here we demonstrated that the catalyst performance is significantly improved by removing the inhibiting carboxyl groups from the carbon material. We expect that this work will pave the way for further development of carbon-based catalysts for ODH reactions to offer robust alternatives for transition metal mediated reactions.
