Abstract

We consider a two-planet system, which migrates under the influence of dissipative forces that mimic the effects of gas-driven (Type II) migration. It has been shown that, in the planar case, migration leads to resonant capture after an evolution that forces the system to follow families of periodic orbits. Starting with planets that differ slightly from a coplanar configuration, capture can, also, occur and, additionally, excitation of planetary inclinations has been observed in some cases. We show that excitation of inclinations occurs, when the planar families of periodic orbits, which are followed during the initial stages of planetary migration, become vertically unstable. At these points, vertical critical orbits may give rise to generating stable families of 3D periodic orbits, which drive the evolution of the migrating planets to non-coplanar motion. We have computed and present here the vertical critical orbits of the 2/1 and 3/1 resonances, for various values of the planetary mass ratio. Moreover, we determine the limiting values of eccentricity for which the “inclination resonance” occurs.

keywords inclination excitation, type II migration, periodic orbits, vertical stability, planetary systems.
1 Introduction

In the last fifteen years, many studies have been devoted to planetary radial migration, induced by the interaction with the gaseous protoplanetary disk (commonly referred to as “Type II” migration, when the planetary masses are of the order of the Jovian mass). A common conclusion is that such migration leads with high probability to resonant capture and this may explain why many planets in extrasolar systems are found to be locked in resonance, see e.g. (Haghighipour 1999; Lee and Peale 2002; Nelson and Papaloizou 2002; Kley 2003; Papaloizou 2003).

Planet migration is a complex process that cannot be viewed independently from the planet formation process. Some models suggest that capture in resonance can occur during the phase of ”Type I” (fast) migration, while the planets are still small in mass (embryos), (see e.g. Correa-Otto et al. 2013). However, planets that are nearly fully formed and have large masses can also be captured in resonance, during the subsequent phase of slow (Type II) migration, as has been seen in many simulations. For example, such a process (capture of Jupiter and Saturn in a 3/2 or 2/1 resonance) has been shown in simulations to produce the necessary initial set-up for the ”Nice model” of solar system evolution (see Morbidelli and Crida 2007).

The dynamics of a two-planet system under a ‘slow’ dissipation have been studied in various approximations. In the secular approximation, Michtchenko and Rodríguez (2011) have shown that the two-planet system evolves along the corresponding stationary solutions of the secular equations, owing to the exchange of angular momentum between the planets and the external medium (disc); the angular momentum deficit (AMD) is an adiabatic invariant of the system. Similarly, near a resonance, a new action, $J$, conjugate to the resonant angle $\sigma$ can be defined as an adiabatic invariant. The use of adiabatic invariance in problems of tidal migration and resonance crossing in the restricted three-body problem was pioneered by (Henrard 1982; Henrard and Lemaitre 1983) and generalized to the case of two massive satellites by Peale 1986. As also shown in (Morbidelli et al. 2009) for the case of a two-planet system, when the critical curve of the resonance is crossed, $J$ suffers a very small jump and approximately is preserved, inside the resonance domain; the former action (e.g. the AMD) is no longer preserved. The system evolves along the resonant stationary solutions, moving from one energy level to the other, while the amplitude of oscillations around the equilibrium is nearly preserved. Note that each resonance is defined by a different critical argument and therefore, a different action that will serve as the new invariant, if several resonances are crossed under the action of a dissipative force. At each resonance crossing, the osculating elements suffer from instantaneous
'jumps' that are roughly independent of the crossing speed and can be large or small, depending on the geometry of the critical curve in phase space.

During resonant capture and as converging migration still proceeds, the eccentricities of the planets increase as a consequence of the preservation of an adiabatic invariant mentioned above. Presenting the evolution of the system in the eccentricities plane, we can obtain particular migration paths, that depend on the planetary mass ratio. These paths follow closely the stationary stable solutions of the averaged planetary three-body problem (as shown in Ferraz-Mello et al. 2003, Lee 2004, Beaugé et al. 2006). Seen from a different point of view, these stationary solutions correspond to resonant, stable, periodic orbits of the general three body problem in a rotating frame. Therefore, the long-term evolution paths followed by a migrating two-planet system are described by families of stable periodic orbits (Hadjidemetriou and Voyatzis 2010, 2011).

All the above mentioned studies assume coplanar planetary motion. Introducing a non-zero mutual inclination in a system, one could claim that the former stability of the system is not affected, since the average distance of the planets increases. However, this is not generally true and a small inclination may destabilize a planetary system, as in Ferraz-Mello et al. 2005). Regular evolution of inclined systems is expected in phase space islands around 3D stable families of periodic orbits (Antoniadou and Voyatzis 2013, Thommes and Lissauer 2003) showed that 3D stable configurations can be obtained after migration and resonant capture in the 2/1 resonance, starting from a two-planet system of nearly (but not exactly) coplanar orbits. In that work, it was observed that, when the system reached particular high-enough values of the eccentricity, an excitation of the mutual inclination took place; thus, the system reached a so-called “inclination resonance”. As long as the system remains nearly planar, it follows closely a path that is determined by the planar stationary solutions (which can be asymmetric). Numerical simulations (Lee and Thommes 2009) showed that sudden “jumps” to nearby paths, with the outer planet typically being more eccentric than the inner one, can occur, leading to inclination excitation under particular circumstances. These paths can be identified as families of asymmetric periodic orbits (see e.g. Voyatzis et al. 2009). Considering reasonable values of the migration and eccentricity damping rates Libert and Tsiganis 2009 showed that capture to other resonances (e.g. 3/1, 4/1 and 5/1) can also lead to inclination excitation, when eccentricity damping is not very strong.

In this study, we show an intrinsic property of the three body problem dynamics that causes the inclination excitation and determine the particular regions in phase space, where it takes place. In particular, we show that vertical instability of periodic orbits along which a planetary system migrates,
can excite the system away from its planar motion. Such a vertical instability occurs at vertical critical orbits (or briefly, vco) where families of 3D periodic orbits bifurcate. In the next section, we present a brief description of our model and its periodic orbits and discuss the notion of vertical instability. In Sect. 3, we compute and present the vertical stability property for the family of circular periodic orbits and for the 2/1 and 3/1 resonances. In Sect. 4, we perform numerical simulations of a migrating two-planet system, which evolves along the circular family and then, is captured to either the 2/1 or the 3/1 resonance. We show that, for reasonable values of the migration rate, such two-planet systems can naturally reach non-zero values of mutual inclination, provided that the eccentricity damping rate is not very strong. Finally, we conclude and discuss the orbital features that such an inclined system should possess, if produced by differential migration.

2 Periodic orbits and vertical instability

We consider a two-planet system and study its dynamics in the general three body problem, consisting of a star, \( S \), with mass \( m_0 \), and two planets, \( P_1 \) and \( P_2 \) with masses \( m_i \ll m_0 \), \( i = 1, 2 \). Indices 0, 1 and 2 will always indicate quantities of the star, the inner and the outer planet, respectively. By introducing a rotating frame of reference \( Gxyz \), which rotates around the constant angular momentum vector and contains always the bodies \( S \) and \( P_1 \) in the plane \( Gxz \), the position of the system is determined by the four variables \((x_1, x_2, y_2, z_2)\) (see Michalodimitrakis 1979; Antoniadou and Voyatzis 2013). Thus, we obtain a four degrees of freedom Lagrangian

\[
\mathcal{L} = \mathcal{L}(q, \dot{q}), \quad q = \{x_1, x_2, y_2, z_2\},
\]

and particularly,

\[
\mathcal{L} = \frac{1}{2}(m_0+m_1)[a(\dot{x}_1^2+\dot{y}_1^2+\dot{z}_1^2)+b((\dot{x}_2^2+\dot{y}_2^2+\dot{z}_2^2)+\dot{\theta}^2(x_2^2+y_2^2)+2\dot{\theta}(x_2y_2-x_2y_2))] - V,
\]

where \( m = m_0 + m_1 + m_2 \), \( a = m_1/m_0 \), \( b = m_2/m \), \( V = -\frac{m_0 m_1}{r_{01}} - \frac{m_0 m_2}{r_{02}} - \frac{m_1 m_2}{r_{12}} \) is the potential with \( r_{ij} \) indicating the distance between the bodies \( i \) and \( j \).

The angle \( \theta \), between the rotating and the inertial frame, is a cyclic variable, while variables \( z_1, \dot{z}_1 \) and \( \dot{\theta} \) depend on the variables \( q \) (Antoniadou and Voyatzis 2013).

For the system (1) we can define periodic solutions of period \( T \), \( Q(T) = Q(0) \), where \( Q = \{q, \dot{q}\} \). By studying the evolution on a Poincaré map, defined e.g. by the surface of section \( y_2 = 0 \) with \( y_2 > 0 \), the set of initial
conditions of periodic orbits

\[ Q(0) = \{x_{10}, x_{20}, y_{20} = 0, z_{20}, \dot{x}_{10}, \dot{x}_{20}, \dot{y}_{20}, \dot{z}_{20}\} \]

forms characteristic curves (or families of periodic orbits) in the phase space of the Poincaré map, due to mono-parametric continuation. Linear stability analysis of a periodic orbit is based on the position of the four pairs of conjugate eigenvalues of the monodromy matrix (Skokos 2001).

Planar periodic orbits can be computed in the context of the planar model \((z_2 = \dot{z}_2 = 0)\) and their linear stability is characterized as horizontal stability.

The property of vertical stability of planar periodic orbits has been introduced by Hénon (1973) for the restricted problem and generalized for the general problem by Michalodimitrakis (1979) and Ichtiaroglou et al. (1978).

Let us consider a planar solution \(Q(t)\), which corresponds to the initial conditions \(Q(0)\) with \(z_2(0) = \dot{z}_2(0) = 0\). We expand the equation of motion for \(z_2\) as it is derived by the Lagrangian, around the planar solution assuming a small vertical deviation in the initial conditions \(\delta z_2(0) = \zeta(0)\) and \(\delta \dot{z}_2(0) = \eta(0)\). Then, to first order in terms of the vertical components, the evolution of the deviations is given by the equations

\[ \dot{\zeta} = \eta, \quad \dot{\eta} = A(Q(t))\zeta + B(Q(t))\eta. \]  

(2)

If \(Q(t)\) is a periodic solution of period \(T\), then (2) is a linear system with periodic coefficients and solution of the form

\[ \begin{pmatrix} \zeta(t) \\ \eta(t) \end{pmatrix} = \begin{pmatrix} \zeta_1(t) & \zeta_2(t) \\ \eta_1(t) & \eta_2(t) \end{pmatrix} \begin{pmatrix} \zeta(0) \\ \eta(0) \end{pmatrix} \]  

(3)

where \((\zeta_1, \eta_1)^\top\) and \((\zeta_2, \eta_2)^\top\) forms the fundamental matrix of solutions \(\Delta(t)\) corresponding to the initial deviations \((1, 0)^\top\) and \((0, 1)^\top\) (Ichtiaroglou et al. 1978). The evolution of solutions (3) depends on the eigenvalues of the monodromy matrix

\[ \Delta(T) = \begin{pmatrix} \zeta_1(T) & \zeta_2(T) \\ \eta_1(T) & \eta_2(T) \end{pmatrix} = \begin{pmatrix} a & b \\ c & d \end{pmatrix}. \]

or on the vertical stability index

\[ a_v = \frac{1}{2}(a + d). \]  

(4)

In particular, if \(|a_v| < 1\), the eigenvalues are complex conjugate with modulus 1 and the vertical motion is stable (bounded). If \(|a_v| > 1\) the eigenvalues are real, leading to unbounded solutions (vertically unstable). Periodic
Figure 1: **a** The variation of stability index along the 2/1 resonant family of planar periodic orbits for $\rho = 0.5$ (family is parametrized by $e_1$). The vco is located at $e_1 = 0.6$ ($e_2 = 0.27$). The indicated orbit-1 ($e_1 = 0.5$, $e_2 = 0.21$) and all orbits on the left of vco are vertically stable (vs); orbit-2 ($e_1 = 0.65$, $e_2 = 0.3$) and all orbits on the right of vco are vertically unstable (vu). The red coloured section corresponds to horizontally unstable orbits **b** The evolution of planetary inclinations of the planar orbit-1 that is initially perturbed vertically by $\Delta i(0) = 5^\circ$. **c** The same for orbit-2 initially perturbed by $\Delta i(0) = 0.1^\circ$.

Orbits with $|a_v| = 1$ are *vertical critical orbits* (vco) and, in general, constitute critical planar orbits from which families of 3D periodic orbits bifurcate (Ichtiaoglou and Michalodimitrakis 1980 | Antoniadou and Voyatzis 2013).

In general, $a_v$ varies along a family of planar periodic orbits and we may obtain none, one or more vco along the family. In Fig. 1a, we present the variation of $a_v$ along a part of the 2/1 resonant symmetric family (see also Fig. 1b) for mass ratio $\rho = m_2/m_1 = 0.5$ and configuration $(\theta_1, \Delta \varpi) = (0, 0)$, where $\theta_1 = \lambda_1 - 2\lambda_2 + \varpi_1$ is a resonant angle and $\Delta \varpi = \varpi_2 - \varpi_1$ is the relative longitude of the periapse. Here, the family is parametrized by the eccentricity $e_1$. We obtain one vco at $(e_1^*, e_2^*)=(0.6, 0.27)$. Orbits with $e_1 < e_1^*$ or $e_1 > e_1^*$ are vertically stable or unstable, respectively. By choosing initial conditions of a vertically stable orbit, e.g. a planar periodic orbit of the family at $(e_1, e_2)=(0.5, 0.21)$, and by adding a small initial vertical deviation corre-
Figure 2: Poincaré map projections in the plane \((z_2, \dot{z}_2)\) of a vertically stable orbits \((orbit-1)\) starting with a vertical deviation from plane given by the values \(\Delta i(0)\) b two vertically unstable orbits starting with the same initial planar conditions \((orbit-2)\) and with a very small initial vertical deviation \(\Delta i(0)=0.1^\circ\). The two orbits have been chosen so that they follow the unstable manifolds of both directions.

Corresponding to a mutual planetary inclination \(\Delta i(0) = 5^\circ\) (and \(\Delta \Omega = 180^\circ\)) we obtain regular, small-amplitude oscillations of the planetary inclinations (Fig. 1b). Instead, if we consider the initial conditions of the planar periodic orbit \((e_1, e_2)=(0.65, 0.3)\) and add a very small vertical deviation \(\Delta i(0) = 0.1^\circ\), we obtain an excitation of the planetary inclinations, which now oscillate irregularly with relatively large amplitude. Also, we depict the above samples of trajectory evolution in the projection plane \((z_2, \dot{z}_2)\) of the Poincaré map (Fig. 2). In the case of vertical stability (left panel), we see that, even for large initial vertical deviations (up to \(15^\circ\) of mutual inclination), the evolution is regular, showing vertical oscillations around the planar periodic orbit. In the case of vertical instability, a saddle-like picture is obtained, showing relatively large vertical deviations from the plane \(z = 0\).

3 Vertical critical orbits in planetary dynamics

In this section, we compute and present \(vco\) in three cases, particularly for circular planetary orbits, 2/1 and 3/1 resonant orbits. The planar families of these orbits and their horizontal stability have been given in previous works,
3.1 The circular family

The circular family of periodic orbits of the restricted problem can be continued with respect to the mass in the general problem (Hadjidemetriou 2006; Voyatzis et al. 2009) without structural changes, for small planetary masses. The mean motion ratio $n_1/n_2$ varies along the circular family, which shows gaps at the 1st order resonances $(n + 1)/n$, $n \in \mathbb{Z}$. For $n_1/n_2 \gtrsim 2/1$ we have the family segment $C_I$ (see Fig. 3a), which consists of stable orbits except for a small section at the 3/1 resonance, where the circular orbits become unstable. At the 2/1 resonance the family continues smoothly to the elliptic 2/1 resonant family $S_{I}^{2/1}$. For $n_1/n_2 \lesssim 2/1$ the family segment $C_{II}$ exists, which continues smoothly to the elliptic resonant families $S_{II}^{2/1}$ and $S_{II}^{3/2}$ (to the right and to the left, respectively). A small horizontally unstable section of $C_{II}$ appears close to the 5/3 resonance.

The variation of the vertical stability index, $a_v$, along the circular family is shown in Fig. 3b. At the segment $C_I$ we obtain that $a_v < -1$ in a small segment near the 3/1 resonance. Thus, both the vco’s ($a_v = -1$) and the vertically unstable orbits are horizontally unstable. A similar situation holds as it is mentioned for each case in the following.
for $C_{II}$ at the $5/3$ resonance.

Similar results with those presented in Fig. 3 have been obtained for various mass ratios and for values of the planetary masses up to $5 M_J$, where $M_J$ is the Jovian mass.

### 3.2 The $2/1$ resonance

As mentioned above, from the circular family we obtain the resonant families $S^{2/1}_I$ and $S^{2/1}_{II}$ of symmetric periodic orbits. The family $S^{2/1}_{II}$ is horizontally unstable and terminates at a collision orbit. Thus, we examine only family $S^{2/1}_I$ for various values of the mass ratio $\rho = m_2/m_1$, as depicted in Fig. 4a, in the projection plane of eccentricities. The properties of these families are described in Beaugé et al. (2006), Voyatzis and Hadjidemetriou (2005) and Voyatzis et al. (2009). The families start from the circular family, $(e_1, e_2) \approx (0, 0)$ as stable, but for $\rho \lesssim 1$ they turn into horizontally unstable at particular eccentricity values. Hence, we obtain an unstable segment which terminates at higher eccentricities and the orbits become stable again.

At the points where the stability changes, families of asymmetric periodic orbits bifurcate. For $0.37 \lesssim \rho \lesssim 1$, we obtain the family $A^{2/1}_a$, which forms a bridge connecting the two bifurcation points of the family $S^{2/1}_I$. For $\rho < 0.37$, a bifurcation occurs and we obtain the asymmetric families $A^{2/1}_a$ and $A^{2/1}_b$.

We have computed and present here (also in Fig. 4a) the vertical critical orbits and the family segments that are vertically unstable. In family $S^{2/1}_I$, there exist horizontally stable $vco$’s for $e_1 > 0.5$ and $\rho > 0.12$. In family $A^{2/1}_a$, we obtain a bifurcation of $vco$ at the critical mass ratio value $\rho^* \approx 0.43$. Thus, for $\rho > \rho^*$ no $vco$ exists on the asymmetric family, which is always vertically stable. For $\rho < \rho^*$ two $vco$’s exist in $A^{2/1}_a$, which form a family section of vertically unstable orbits between them. These $vco$’s seem to continue also in family $A^{2/1}_b$. In family $A^{2/1}_d$, we have found one $vco$ located at a low (resp. high) eccentricity value for the inner (resp. outer) planet.

### 3.3 The $3/1$ resonance

It has been shown that four $3/1$ resonant families of periodic orbits bifurcate from the circular family $S^{3/1}_I$ (Voyatzis and Hadjidemetriou 2006, Michtchenko et al. 2006, Voyatzis 2008). From these families, only family $S_4$ starts from the circular family as stable for all values of the mass ratio $\rho$. Its characteristic curves in the eccentricities plane are shown in Fig. 4b, for some typical values of $\rho$. For any value of $\rho$, the family becomes horizontally unstable at a particular eccentricity value, which depends on $\rho$. At these
Figure 4: Families of a 2/1 and b 3/1 resonant periodic orbits. Blue and red colour indicate horizontal stability and instability, respectively. The circles indicate vco and the sections of magenta colour consist of vertically unstable orbits. For each curve the corresponding mass ratio $\rho = m_2/m_1$ is indicated.

points bifurcation of the asymmetric family $A_{3/1}^{4}$ occurs, consisting of stable orbits (at least in the eccentricities domain of Fig. 4b). The vco’s in the above mentioned families and the vertically unstable parts are also indicated in Fig. 4b. We can see that symmetric vco’s are all horizontally unstable up to $\rho \approx 6.5$ and located at $e_1 \gtrsim 0.6$. Family $A_{3/1}^{4}$ has, also, one vco at a given point in $(e_1, e_2)$; as $\rho$ increases, $e_1$ also increases, while $e_2$ decreases.

4 Vertical instability during planetary migration

As we mentioned in the introduction, planetary migration, caused by planet-disc interactions, will force a nearly circular, planar two-planet system to evolve in phase space along the stable families of periodic orbits. Lee and Thommes (2009) showed that this, also, holds for systems starting with slightly inclined orbits, but an inclination resonance may occur at some point.

In this section, we wish to study the time evolution of a nearly (but not

---

1For $\rho \gtrsim 6.5$, the vco enters the stable segment of $S_{3/1}^{4}$. 

10
exactly) coplanar system of two planets, under the effects of radial (presumably, gas-driven) migration. To do this, we consider the planetary three-body problem, but impose a Stokes-type dissipative force on the outer planet that mimics the effects of Type II migration (Beaugé and Ferraz-Mello 1993; Beaugé et al. 2006) of the form

$$F_d = -C(v_p - \alpha v_c)$$

where $v_p$ is the planar velocity component of the planet and $v_c$ is the circular velocity at the particular distance of the star. The positive constants $C$ and $\alpha$ are associated in a first order approximation with the migration rate in semi-major axis, $\nu$, and the eccentricity damping, $K$, according to the formulae (Beaugé and Ferraz-Mello 1993; Beaugé et al. 2006)

$$\nu = 2C(1 - \alpha), \quad K = \frac{\alpha}{2(1 - \alpha)}.$$

We performed a series of numerical simulations, with star mass $m_0 = 1M_\odot$, starting with almost circular and co-planar orbits, i.e. $e_1(0) = e_2(0) = 0.01$, $i_1(0) = i_2(0) = 0.1^\circ$, and $\Delta\Omega = 180^\circ$. The inner planet is always set to $a_1(0) = 5$ AU. We examine two cases for the initial position of the outer planet (i) $2/1 < n_1/n_2 < 3/1$ (interior to the 3/1 resonance) and (ii) $n_1/n_2 > 3/1$ (exterior to the 3/1 resonance). Also, following Libert and Tsiganis (2009), where the formula concerning the order of migration rate given by Ward (1997) is used, we consider parameter values in the intervals $10^{-7} \leq \nu \leq 10^{-5} (y^{-1})$ and $0.5 \leq K \leq 100$. However, the typical dynamics presented in the following is revealed for small values of migration rates, particularly for about $\nu \lesssim 10^{-6} y^{-1}$, and for sufficiently small eccentricity damping $K$, in order for the system to reach the necessary eccentricity values.

Since we always start with orbits close to the circular family $C_I$, the dissipative forces cause a slow slide of the system along the family $C_I$ (i.e. the planetary orbits remain nearly circular) and towards lower mean motion ratio values (inward migration). When we start below the 3/1 resonance, the system enters the family $S_{2/1}^I$ and is captured in the 2/1 resonance. Starting above the 3/1 resonance, we approach the 3/1 resonance where the $C_I$ becomes horizontally unstable and contains also vertical critical points. However, the system slides into the $S_{3/1}^I$ resonant family, which is the only stable one, and 3/1 resonant capture occurs. During the migration of the system along the family $C_I$, for both cases, we have vertical stability and therefore, the orbits remain almost planar. We note that, apart from 2/1 and 3/1, capture to other resonances has not been observed in our set of simulations.
Figure 5: Evolution of orbital elements under the influence of the dissipative force (5) with $\nu = 4.2 \times 10^{-6}\text{yr}^{-1}$, $K = 1$ and planetary masses $m_1 = 1 \text{M}_J$, $m_2 = 2 \text{M}_J$. Blue and red colour lines refer to the inner ($P_1$) and the outer planet ($P_2$), respectively. (a) semimajor axes $a$, (b) the mean motion ratio, (c) eccentricities $\epsilon$, (d) inclinations and mutual inclination, $i$, (e) the apsidal difference $\Delta \varpi$, (f) the resonant angle $\phi_1$ (similar evolution is observed for $\phi_2$).
Figure 6: The evolution shown in Fig. 5 is now presented in the space $e_1 - e_2 - \Delta i$. When the system is captured in the resonance 2/1 (approximately at zero), it evolves along the path indicated by the family $S_{2/1}^1$. The eccentricities increase, while the inclinations remain at low values. When the $vco$ is reached the inclinations start to increase and the system follows the family $F_{2/1}^3$ of 3D periodic orbits.
4.1 2/1 resonance capture

After 2/1 resonant capture occurs, the system follows the family $S_{1}^{2/1}$. If the system has mass ratio $\rho > 1$, it does not leave the symmetric family and reaches the corresponding $vco$, located at $e_1 > 0.5$. A typical example of such an evolution is shown in Fig. 5 for $\rho = 2, \nu = 4.2 \times 10^{-6}y^{-1}$ and $K = 1$. Resonant capture takes place at $t \approx 40Ky$, with the eccentricities remaining low up to that time. After getting captured, the eccentricities of the planets start increasing, but the orbits still remain planar. At $t \approx 360Ky$, the inclination resonance is reached and the planetary orbits become mutually inclined. At the inclination resonance, we have $e_1 = 0.63$ and $e_2 = 0.26$; these values correspond to the position of the $vco$ of the family $S_{1}^{2/1}$. As the inclination starts to increase the particular resonant angles $\varphi_i = 2\lambda_1 - 4\lambda_2 + 2\Omega_i$ ($i = 1, 2$) librate around $180^\circ$ indicating, beside the libration of $\Delta \varpi$ around $0^\circ$ the symmetric configuration of the system.

It is clear from Fig. 5 that the system evolves in a way similar to that discussed in the Introduction. When the critical mean motion ratio 2/1 is reached along the circular family (at $t \approx 40 Ky$), a gap is met and the system turns from the family of circular periodic orbits to the 2/1-resonant family of eccentric periodic orbits (see Sect. 3.1). The AMD is no longer a proper invariant; the resonant action (conjugate to the resonant angle) is the invariant that will be approximately preserved inside this particular resonance domain. When the critical curve of the 2/1-inclination resonance is reached (i.e. the $vco$) a similar pattern is observed due to the bifurcation of the 3D family of periodic orbits. The new action (conjugate to the critical angle of the 2/1-inclination resonance) will be now preserved; for $t > 400 Ky$, the inclinations increase as migration goes on. The only appreciable difference between the two resonance crossings that the system suffers is in the initial 'jump' in osculating elements. We mention that in the planar problem the passage from the circular family to the elliptic resonant family is quite smooth (due to the formed gap, see Fig. 3), but in the passage from the planar to the 3D family we have a bifurcation point at the $vco$ that causes an abrupt change in the inclination. Also, one can see in Fig. 2b, that the area enclosed by the 'separatrix' is much wider than before this bifurcation occurs (where no separatrix exists), and thus the change in osculating inclination upon the $vco$ crossing has to be large, if the system has initially nearly zero inclinations.

If we present the evolution in the space $e_1 - e_2 - \Delta i$ (see Fig. 6), we observe that the inclination starts to increase, when the $vco$ is reached and the family becomes, thereafter, vertically unstable. In particular, we observe that the evolution follows the family $F_{1}^{2/1}$ of 3D orbits, which bifurcates from the $vco$. As seen from the nearly vertical intersection between the planar and...
3D families, crossing of the \textit{vco} implies that small variations in eccentricity will be accompanied by large variations in inclination.

For $0.43 < \rho < 1$, the evolution follows the asymmetric branch $A_{\alpha}^{2/1}$, when $S_1^{2/1}$ becomes horizontally unstable (see Fig. 4a). Since $A_{\alpha}^{2/1}$ ends again at the stable part of $S_1^{2/1}$, the evolving system meets again the \textit{vco} of the symmetric family at $e_1 > 0.5$. The excitation of inclination occurs again, when the \textit{vco} is reached.

We remind the reader that for mass ratios $\rho < \rho^*$, where $\rho^* = 0.43$, vertical critical orbits exist along the family $A_{\alpha}^{2/1}$. Thus, the inward migration for $0.37 < \rho < \rho^*$ may lead to the \textit{vco} of this family, which is located at a relatively low eccentricity value, $e_1 (\lesssim 0.2)$. For $\rho < 0.37$, the system follows the asymmetric family $A_{\beta}^{2/1}$, which has, also, a \textit{vco} for $e_1 < 0.2$, but for relatively large eccentricity of the outer planet (namely, $e_2 > 0.4$).

The different migration paths, associated with different mass ratios as was discussed above, are presented in Fig. 7a. In all cases the system enters the inclination resonance, when the \textit{vco} is reached. The different loci of the “inclination resonance” for $\rho < \rho^*$ and $\rho > \rho^*$ are clearly distinguished. In Fig. 8 (panels a, b), we present the evolution of resonant angles $\Delta \varpi$ and $\varphi_1$ for $\rho = 0.4 < \rho^*$ and $\rho = 0.5 > \rho^*$. After the capture in the resonance $\Delta \varpi$ librates and when the system enters the inclination resonance $\varphi_1$ also librates. In the first case (panel a), we finally obtain an asymmetric libration for both resonant angles. In the second case (panel b), after a passage from asymmetric librations for $\Delta \varpi$ (along the family $A_{\alpha}^{2/1}$), both angles, $\Delta \varpi$ and $\varphi_1$ librate around $0^\circ$ and $180^\circ$, respectively. So the bifurcation at $\rho = \rho^*$ explains the result of \textit{Lee and Thommes (2009)} that at $\rho \approx 0.4$ the inclination resonance changes from asymmetric to symmetric.

The above types of evolution have been always verified by our simulations for $\nu \lesssim 10^{-6} \, y^{-1}$ and for small eccentricity damping ($K \approx 1$) that permits the sufficient increase of the eccentricities. For larger values of $\nu$, particularly for $\nu = 10^{-5} \, y^{-1}$, we obtained capture in the 2/1 resonant and in most cases temporal inclination resonance followed by large oscillation of the eccentricities, which in a relatively short time interval destabilizes the system and the evolution becomes strongly irregular. We observed that it is possible even for $\rho < \rho^*$ the evolution to overcome the asymmetric \textit{vco} and then either the inclination resonance appears when the system reaches the next \textit{vco} located in the symmetric family or the system jumps in an other family of periodic orbits. Such complicated phenomena, which are possible for reasonable values of the migration rate, have been noticed and discussed in \textit{Lee and Thommes (2009)}. 

15
Figure 7: The evolution after a $2/1$ and b $3/1$ resonant capture presented in the space $e_1 - e_2 - \Delta i$. Four different cases are presented, which correspond to the indicated planetary mass ratio values. It is $\nu = 4.2 \times 10^{-7}$ $y^{-1}$ and $K = 1$ (except for $\rho = 0.3$ where $K = 0.5$ in $2/1$ resonant capture and for $\rho = 0.5$ where $K = 0.5$ in $3/1$ resonant capture). The increase of mutual inclination occurs, when the system reaches a vco.
Figure 8: The evolution of the resonant angles $\Delta \varpi$ and $\varphi_1$, for the indicated resonance and mass ratio $\rho = \frac{m_2}{m_1}$ and for $\nu = 10^{-6} \, \text{y}^{-1}$, $K = 1$. After the capture in the resonance $\Delta \varpi$ librates and after the inclination resonance $\varphi_1$ also librates. Librations take place around $0^\circ$ or $180^\circ$ (symmetric configuration) or around a different value (asymmetric configuration).
4.2 3/1 resonance capture

In the 3/1 resonance, the system migrates along the family $S_{3/1}^4$. When this family becomes horizontally unstable, the system follows the asymmetric family $A_{3/1}^4$, which starts both as horizontally and vertically stable (see Fig. 4b). As we have mentioned, along family $A_{3/1}^4$ a vco exists, for any mass ratio value. There the family becomes vertically unstable and the inclination resonance occurs. Fig. 7b shows the evolution in the space $e_1 - e_2 - \Delta i$ for different values of $\rho$. An increase of the mutual inclination occurring when the vco is reached is clearly seen in all cases. Also, in Fig. 8 (panels c,d), we present the evolution of resonant angles $\Delta \varpi$ and $\varphi_1 = \lambda_1 - 3\lambda_2 + 2\Omega_1$. For $m_1 = m_2$ (panel c) $\Delta \varpi$ librates around 180° after the 3/1 resonance capture in family $S_{3/1}^4$ and then its librations become asymmetric (bifurcation to the family $A_{3/1}^4$). Angle $\varphi_1$ starts to librate around 290°, when the system reaches the vco. The inclination resonance becomes symmetric for $\rho = 10^{2.5}$ as it is shown in panel (d), where $\varphi_1$ librates around 0° after 600 Ky, where the inclination resonance takes place. However, after about 1.2 My the evolution becomes quite irregular and the angles show rotations.

Differential migration with positive eccentricity damping generally seems to reach an asymptotic limit at some point in the $(e_1, e_2)$ plane (Lee and Peale 2002; Kley 2003). This point depends on the values of the migration rate, $\nu$, and eccentricity damping rate, $K$. In the case of $\rho = 0.5$ shown in Fig. 7b, we have $K = 0.5$ (in contrast to the remaining cases, where $K = 1$). If for the same initial conditions we also used $K = 1$, then the system would stall at $(e_1, e_2) \approx (0.15, 0.4)$ and therefore, the vco of this particular family would not be reached and inclination excitation would not occur. The same situation holds also in the 2/1 resonance (see Fig. 7a) for $\rho = 0.3$.

Our numerical simulations showed that the capture in the 3/1 resonance requires quite slower migration rates compared to those for the 2/1 case and depends significantly on the planetary mass ratio, $\rho$. Particularly, for $K = 0.5$ and $\nu = 10^{-6} \, y^{-1}$ or $\nu = 5 \times 10^{-7} \, y^{-1}$ capture in the 3/1 resonance is observed only for $\rho \lesssim 0.8$ or $\rho \lesssim 0.5$, respectively. When the system is captured in the 3/1 resonance, then the paths defined by the particular families of periodic orbits are followed by the evolution and inclination resonance always occurs, if the eccentricity damping is sufficiently small ($K \lesssim 1$) for the system to reach the vco.

\footnote{Particularly we used $m_1 = 0.0005$ and $m_2 = 0.005$. We remind that for $\rho \gtrsim 6.5$, the vco belongs to the stable part of the family $S_{3/1}^4$.
5 Conclusions and discussion

Previous studies have shown that planet migration induced by tidal interactions between Jovian-sized planets and the gaseous protoplanetary disc, takes place along specific paths in phase space, formed by stable families of periodic orbits. In this paper, we considered the spatial case of the three-body problem, in order to describe possible effects of migration on the mutual inclination of two-planet systems.

We computed the vertical stability index along families of planar periodic orbits and determined the vertical critical orbits ($vco$). Orbits with initial conditions in the neighbourhood of a horizontally and vertically stable periodic orbit, evolve regularly, showing very small oscillations in the inclinations. However, in the neighbourhood of vertically unstable periodic orbits, the initially small mutual planetary inclination may increase to high values, depending on the mass ratio, as well as the mean motion ratio of the two planets.

We showed that the “inclination resonance”, which was observed in the numerical simulations of Thommes and Lissauer (2003), Lee and Thommes (2009) and Libert and Tsiganis (2009), should be associated with the existence of $vco$’s along the corresponding planar family of resonant periodic orbits. In particular, when an initially almost planar system migrates along a horizontally and vertically stable family of periodic orbits, the initial small inclinations show oscillations of very small amplitude. When, a $vco$ is reached the inclinations start to increase rapidly. The position of a $vco$ along a family of periodic orbits depends on the planetary mass ratio, $\rho$.

We particularly studied the $2/1$ and $3/1$ resonant captures. The families of periodic orbits for these resonances (and various values of $\rho$) have $vco$’s, which can give inclination excitation, when they are reached by differential migration. The distribution of these $vco$’s in the eccentricities plane is different for these two resonances and is presented in Fig. 9. For the $2/1$ resonance, we obtain two distinct regions of $vco$’s, $R_1$ and $R_2$. In region $R_1$, the eccentricity of the outer planet is larger than the inner one. This region can be reached by a migrating system with mass ratio $\rho < 0.43$. For larger mass ratios, the system reaches the region $R_2$, where the orbit of the inner planet is quite more eccentric than the orbit of the outer one.

In the $3/1$ resonance, the $vco$’s seem to be located approximately on a straight line in the plane of eccentricities. As $\rho$ increases, $e_1$ increases and $e_2$ decreases. This relationship can be expressed by a linear fit of the form $e_2 = 0.69 - 0.73e_1$. For $\rho \lesssim 6.5$, the $vco$’s that drive migration belong to the asymmetric families of periodic orbits, while for larger mass ratio values, they belong to the symmetric families, $S_{3/1}$. 
Figure 9: The position of $vco$ related to inclination resonance after differential migration. The corresponding planetary mass ratio, $\rho$, is indicated for each $vco$ a 2/1 resonance: two distinct regions of $vco$ are obtained b 3/1 resonance: the $vco$ are located on a straight line in the plane of eccentricities (the least square fitting is presented).

We note that a similar relation between the onset of inclination excitation and the values of the planetary eccentricities was pointed out by Libert and Tsiganis (2009), who suggested that, for inclination excitation to occur, at least one of the two planets has to have an eccentricity larger than $\gtrsim 0.4$. Here, we further quantify this relationship. Moreover, we show that it is a direct consequence of the distribution of $vco$’s in the eccentricities plane, for different mass ratios. Our results offer a possible diagnostic tool for 2/1- and 3/1-resonant systems: if the mass ratio and the eccentricities are known, then, we can tell if the system had passed through a $vco$ and thus, would have a non-zero mutual inclination.

Differential migration generally seems to stall, reaching an asymptotic limit in $(e_1, e_2)$; beyond this point in time no further increase of the eccentricities occurs. This limit and the time that the systems takes to reach it depend on the migration parameters. In the 2/1 and 3/1 resonances studied in this paper, generally the $vco$’s appear for relatively high eccentricity values of one of the two planets. Thus, a necessary condition for the inclination resonance to occur is that the differential migration can be sustained for long-enough times and is sufficiently ‘strong’, as to bring the system at the $vco$ position. As our numerical results suggest, this will be true for small
values of the eccentricity damping rate, $K$. When fast eccentricity variations along migration cause ‘jumps’ to other regions in phase space, whence capture to different families occurs, the presence of vertical instability in these families should excite the inclinations.

In our model we considered a simplified model to describe the interaction of the planets with the gaseous protoplanetary disc, which is better suited for a planar model, rather than a 3D one. When the system becomes inclined, the dissipative forces assumed here do not adequately describe the averaged planet-disc interactions. Thus, although we are confident about the occurrence of vertical instability on the $\nu_0$’s, we cannot safely conclude what are the maximum values of mutual inclination that a particular system could reach.
