The mitochondrial F-type ATPase is a reversible nano-engine responsible for ATP synthesis/hydrolysis, morphology of inner mitochondrial membrane (IMM) by shaping cristae ridges, and fulcrum of the molecular events that trigger cell death by permeability transition pore (PTP) opening [1]. Recently the cryo-EM structures of the entire mammalian complex allowed to identify the different substeps of the rotational state and improved knowledge on some up to now misinterpreted subunits of the membrane domain F<sub>O</sub> [2,3]. Moreover, the different conformational states of the Ca<sup>2+</sup>-activated F<sub>F</sub>F<sub>0</sub>-ATP(hydro)lase activity, undetected in the presence of the natural cofactor Mg<sup>2+</sup>, may constitute subsequent steps of a gradual PTP formation [2].

The F-type (F<sub>F</sub>,F<sub>0</sub>) ATPase is composed of a hydrophilic catalytic F<sub>F</sub> domain protruding in the IMM matrix, where ATP synthesis/hydrolysis takes place, and a membrane-embedded F<sub>0</sub> domain that drives H<sup>+</sup> translocation (Fig. 1A). The two domains are functionally and structurally connected by a central stalk which rotates within F<sub>F</sub> and by a peripheral stalk (PS) that extends laterally for the entire enzyme complex height and acts as a stator. This molecular machine transduces the proton motive force, generated by substrate oxidation during mitochondrial respiration, by torque generation to chemical energy stored in the ATP form and vice versa [4].

The F<sub>0</sub> domain consists of c subunits that form an annular structure, the c<sub>r</sub>-ring, which in association with the α subunit, establishes the H<sup>+</sup> translocation pathway [5]. The c-ring is linked to γ, δ, and ε subunits that extend from the IMM to the globular hexamer catalytic sector F<sub>F</sub>. Here, three catalytic β subunits alternate with three non-catalytic α subunits, sequentially changing their conformation as the rotor rotates, namely β<sub>0</sub> (empty), β<sub>TP</sub> and β<sub>DP</sub>, which differ in their affinities for nucleotides. The non-catalytic sites also undergo the three conformational states α<sub>T</sub>, α<sub>TP</sub> and α<sub>DP</sub> always occupied by adenine nucleotide [6]. The rotation direction of the rotor, transmitted to F<sub>F</sub> by the central stalk, is anticlockwise, viewed from the matrix side, when ATP is built by ADP and Pi. As widely known, the enzyme catalysis is reversible and in the reverse mode the rotor rotates clockwise when ATP is hydrolyzed and the enzyme pumps H<sup>+</sup> to re-energize the IMM. This reversal can occur under physiological and pathological conditions. The rotor rotation changes the properties of the three catalytic sites, namely their affinity for adenylate nucleotides, each 120° Thus, in the forward mode, each 360° rotation produces three ATP molecules. During the catalytic cycle of ATP hydrolysis the rotational states of mammalian mitochondrial F<sub>F</sub>-ATPase observed within a single 120° rotation shows 90° and 30° substeps, which differ from bacterial ones (80° and 40°, respectively) [7]. Recent advances pointed out that in mitochondria the first 90° substep is split into other 65° and 25° steps and then the second 30° substep completes one of the three rotational states [2]. The catalytic cycle during one 120° rotation consists of different steps, of which each corresponds to distinct rotation angles, namely 0° which corresponds to ATP binding, 65° to Pi release after ADP release, 90° to the catalytic dwell and ATP hydrolysis, which in turn generates the 30° rotation to complete the 120° rotation. All these interconverted events are based on the different subsequent conformations of the three catalytic β subunits. ADP produced by ATP hydrolysis is responsible for the absence of the steady-state F-ATPase activities by remaining entrapped in the β subunits. The adenine nucleotide bound to the non-catalytic α subunits are not essential for ATP synthesis. However, the MgADP inhibited form on the enzyme catalytic sites is only released when ATP binds to the non-catalytic sites [8]. The cryo-EM structure of F<sub>F</sub> domain in MgADP inhibited form obtained by Sazanov’s group also shows MgADP bound to all the three α subunits and in two β subunits in the β<sub>TP</sub> and β<sub>DP</sub> conformations [2]. Therefore, ATP bound to the non-catalytic sites is required during multiple ATP hydrolysis turnover, but in the α subunits

adenine nucleotide exchange (ATP/ADP) may also occur, by allowing switch from active to inhibited enzyme.

The $\alpha_3\beta_3$-spherical domain $F_1$, connected to PS forms the $F_1F_0$-ATPase stator. The $\alpha_3$, $\alpha_6$, $\alpha_5$, and the $\beta_2$ and $\beta_6$ conformations of $a$ and $\beta$ subunits respectively, are joined to the OSCP (Oligomycin Sensitivity Conferring Protein) subunit, while the $\beta$ subunit in the $\beta_2\beta_6$ conformation is only linked to $F_6$ subunit. Moreover, a subunit in $\alpha_6\alpha_5$ conformation also interacts with $F_6$, $b$, and $d$ subunits. The PS starts from OSCP and continues with $F_6$, $d$, $b$, and $A6L$ in the membrane extrinsic stalk region, while the membrane portion consists of $b$ and $A6L$ subunits associated with the supernumerary subunits ($sn$s) $e$, $f$, $g$, and 6.8 proteolipid (PL) [3]. Some $sn$s are involved in the dimeric $F_1F_0$-ATPase structure, namely in the association of two monomers, and in the IMM bending (Fig. 1B). Accordingly, two monomers join to form a dimer and the monomer-monomer interface occupies the area matching the cristae edge. In mammals, the dimerization sites at the matrix side involve a direct $f$-$f$ bond and the 6.8PL subunit of a monomer binds to the $f$ subunit of the other monomer and vice versa. The N-terminal loops from $a$ subunits establish a contact site within the IMM and, at the positive side of IMM (PSI), the dimer is directly linked by $e$-$e$ bond plus the interaction between the 6.8PL subunit and $e$ subunit of different monomers (Fig. 1C). Dimer association in yeast is different from mammals. Indeed, the yeast dimer is held together centrally by $a$ and $i/j$ subunit dimerization motifs and by interactions between $k$ and $e$ subunits on both sides of the supercomplex [9]. Noteworthy, the yeast $i/j$ subunit is the ortholog of mammalian 6.8PL, while the yeast $k$ subunit is the mammalian DAPIT subunit [2,3]. Accordingly, the $a$, $e$, $f$ subunits, and 6.8PL lead to the mammalian $F_1F_0$-ATPase dimerization. The DAPIT subunit, considering its peripheral position in the membrane (Fig. 1B), forms rows of $F_1F_0$-ATPase dimers by side-by-side interactions of adjacent monomers with $g$ and $a$ subunits at the PSI and $g$ subunits in the matrix, which corresponds to the negative side of the IMM. Moreover, DAPIT promotes the sharp bending of a subunit horizontal helix folded by a conserved proline residue to ensure a tight fit to the $c$-ring and to form the hydrophilic cavity of the half-channel which allows H+ exit. The formation of a larger oligomer, namely the $F_1F_0$-ATPase tetrameric structure, is due to a compact link between two $g$ (within the IMM) and two $e$ subunits (at the matrix side) of two monomers arranged diagonally. The inhibitory factor 1 (IF1), an endogenous protein which inhibits the mammalian $F_1F_0$-ATPase hydrolytic activity at low pHs, when is arranged in the dimeric form joins two $F_1$ domains by targeting the $\beta_2\beta_6$ subunits of adjacent dimers. By such arrangement IF1 plays a structural role by stabilizing the dimer and presumably allows the physiological supramolecular arrangement of $F_1F_0$-ATPases in the mitochondrial membrane [10].

The structural architecture of the single transmembrane helix (H) of $e$ subunit, the H3 of $g$ subunit, and H2 and H3 of $b$ subunit form a BAR-like domain in each monomer that is responsible for IMM bending [9] (Fig. 1D). The tight packing of helices allowed by conserved GxxG motifs on H3e subunit and H3g is stabilized to the H2b by salt bridges, resulting in a compact triple transmembrane helix (TTHM) bundle [2]. Moreover, the H2b joined to H3b helix constitutes the U-turn structure which tilts the TTHM bundle. Interestingly, the $e$ subunit is connected by a terminal lysine to a lipid plug (probably a lyso-phosphatidylserine) in the $c$-ring at the PSI, while the positive charges of Arg38 of c subunits coordinate the phosphatidylinerine at the matrix side. The lipid regions of these two phospholipids are separated by Val16 of c subunits in the IMM core [2].

The dimeric $F_1F_0$-ATPase form, due to interactions between two identical monomers, changes during the catalysis by modifying the curvature of the mitochondrial cristae. When the enzyme is activated by Ca$^{2+}$, which only supports CaATP hydrolysis [11], the Ca$^{2+}$-activated
F1F0-ATP(hydrol)ase causes disassembly/distortion of the entire F1F0 complex with four different conformational states which are not detected when the enzyme is activated by the natural cofactor Mg2+ [2]. The structural modification of the enzyme complex is consistent with the Ca2+-signaling propagation pathway of the Ca2+-activated F1F0-ATP(hydrol)ase that, by undergoing appropriate rotational state(s), promotes the permeability transition pore [11]. The most likely hypothesis is that the channel formation is triggered when the PS accommodates conformational changes of F1 [12] during Ca2+ATP hydrolysis [11]. These conformational changes would generate a force transmitted along the b subunit to TTMH, thus pulling the lipid plug out of the c-ring by the proposed “bent-pull” model [13]. Concomitantly, water molecules fill the c-ring and push the phosphatidylserine on the matrix side (Fig S1). So, the PTP opening, arising from different conformations of the Ca2+-activated F1F0-ATP(hydrol)ase, is consistent with the enzyme monomerization and the disappearance of the cristae [2].

The recent advances on the F1F0-ATPase structures reveal quite unexpected enzyme functions at the molecular level and new biological roles of the enzyme complex in mitochondria [13]. Accordingly, the recently acquired knowledge on the enzyme structure is fully consistent with the Ca2+-activated F1F0-ATP(hydrol)ase participation in the stepwise mechanism of formation and opening of the PTP, which forms by c-ring distortion of and expulsion of the so-called lipid plug [2]. Indeed, the enzyme complex, endowed with dual catalytic roles of ATP synthesis/hydrolysis, structural function in the maintenance of the cristae and functional/stuctural task in the formation of the lethal PTP, constitutes an amazing multitasking mechanism whose multiple functions span from health to mitochondrial diseases and death [14,15].
