ABSTRACT

We have obtained long-slit observations in the optical and near-infrared of 12 circumnuclear \( \text{H} \ II \) regions [circumnuclear star-forming regions (CNSFR)] in the early-type spiral galaxies NGC 2903, 3351 and 3504 with the aim of deriving their chemical abundances. Only for one of the regions, the \( \text{[SIII]} \, \lambda 6312 \, \text{Å} \) was detected providing, together with the nebular \( \text{[S III]} \) lines at \( \lambda \lambda 9069, 9532 \, \text{Å} \), a value of the electron temperature of \( T_e(\text{[S III]}) = 8400^{+4650}_{-1250} \, \text{K} \).

A semi-empirical method for the derivation of abundances in the high metallicity regime is presented.

We obtain abundances which are comparable to those found in high metallicity disc \( \text{H} \ II \) regions from direct measurements of electron temperatures and consistent with solar values within the errors. The region with the highest oxygen abundance is R3\text{+}R4 in NGC 3504, \( 12 + \log(O/H) = 8.85 \), about 1.5 solar if the solar oxygen abundance is set at the value derived by Asplund, Grevesse & Sauval, \( 12 + \log(O/H)_{\odot} = 8.66 \pm 0.05 \). Region R7 in NGC 3351 has the lowest oxygen abundance of the sample, about 0.6 times solar. In all the observed CNSFR the O/H abundance is dominated by the O\textsuperscript{+}/H\textsuperscript{+} contribution, as is also the case for high metallicity disc \( \text{H} \ II \) regions. For our observed regions, however, also the S\textsuperscript{+}/S\textsuperscript{2+} ratio is larger than one, contrary to what is found in high metallicity disc \( \text{H} \ II \) regions for which, in general, the sulphur abundances are dominated by S\textsuperscript{2+}/H\textsuperscript{+}.

The derived N/O ratios are in average larger than those found in high metallicity disc \( \text{H} \ II \) regions and they do not seem to follow the trend of N/O versus O/H which marks the secondary behaviour of nitrogen. On the other hand, the S/O ratios span a very narrow range between 0.6 and 0.8 of the solar value.

As compared to high metallicity disc \( \text{H} \ II \) regions, CNSFR show values of the O\textsubscript{23} and the N2 parameters whose distributions are shifted to lower and higher values, respectively, hence, even though their derived oxygen and sulphur abundances are similar, higher values would in principle be obtained for the CNSFR if pure empirical methods were used to estimate abundances. CNSFR also show lower ionization parameters than their disc counterparts, as derived from the [S II]/[S III]. Their ionization structure also seems to be different with CNSFR showing radiation field properties more similar to \( \text{H} \ II \) galaxies than to disc high metallicity \( \text{H} \ II \) regions.

Key words: ISM: abundances – \( \text{H} \ II \) regions – galaxies: abundances.

1 INTRODUCTION

The inner (~1 kpc) parts of some spiral galaxies show high star formation rates and this star formation is frequently arranged in a ring or pseudo-ring pattern around their nuclei. This fact seems to correlate with the presence of bars and, in fact, computer models which simulate the behaviour of gas in galactic potentials have shown that
nuclear rings may appear as a consequence of matter infall owing to resonances present at the bar edges (Combes & Gerin 1985; Athanassoula 1992).

In general, circumnuclear star-forming regions (CNSFR), also referred to as ‘hotspots’, and luminous and large disc H II regions are very much alike, but look more compact and show higher peak surface brightness (Kennicutt, Keel & Blaha 1989). In many cases they contribute substantially to the emission of the entire nuclear region.

Their large Hα luminosities, typically higher than $10^{39}$ erg s$^{-1}$, point to relatively massive star clusters as their ionization source, which minimizes the uncertainties due to small number statistics when applying population synthesis techniques (see e.g. Cerviño et al. 2002). These regions then constitute excellent places to study how star formation proceeds in high metallicity, high density circumnuclear environments.

In many cases, CNSFR show emission-line spectra similar to those of disc H II regions. However, they show a higher continuum from background stellar populations as expected from their circumnuclear location, often inside 500 pc from the galaxy centre. In early-type spirals CNSFR are also expected to be amongst the highest metallicity regions as corresponds to their position near the galactic bulge. These facts taken together make the analysis of these regions complicated since, in general, their low excitation makes any temperature sensitive line too weak to be measured, particularly against a strong underlying stellar continuum. In fact, in most cases, the [OIII]$\lambda$5007 Å line, which is typically 100 times more intense than the auroral [OIII]$\lambda$4363 Å one, can be barely seen.

Yet, despite its difficulty, the importance of an accurate determination of the abundances of high metallicity H II regions cannot be overestimated since they constitute most of the H II regions in early spiral galaxies (Sa to Scb) and the inner regions of most late-type ones (Sc to Sd) (Diaz 1989; Vila-Costas & Edmunds 1992) without which our description of the metallicity distribution in galaxies cannot be complete. In particular, the effects of the choice of different calibrations on the derivation of abundance gradients can be very important since any abundance profile fit will be strongly biased towards data points at the ends of the distribution. It should be kept in mind that abundance gradients are widely used to constrain chemical evolution models, histories of star formation over galactic discs or galaxy formation scenarios. The question of how high is the highest oxygen abundance in the gaseous phase of galaxies is still standing and extrapolation of known radial abundance gradients would point to CNSFR as the most probable sites for these high metallicities.

Accurate measures of elemental abundances of high metallicity regions are crucial to obtain reliable calibrations of empirical abundance estimators, widely used but poorly constrained, whose choice can severely bias results obtained for quantities of the highest relevance for the study of galactic evolution like the luminosity–metallicity (L–Z) relation for galaxies. CNSFR are also ideal cases to study the behaviour of abundance estimators in the high metallicity regime.

In Section 2 of this paper we describe the sample of regions observed and the circumnuclear environment of their host galaxies. Our observations and the data reduction procedures are described in Section 3. The results are presented in Section 4. The method for the derivation of chemical abundances is described in Section 5. Section 6 is devoted to the discussion of our results. Finally, Section 7 summarizes the main conclusions of this work.

### 2 SAMPLE SELECTION

We have obtained moderate resolution observations of 12 CNSFR in three ‘hotspot’ galaxies: NGC 2903, 3351 and 3504 whose main properties are given in Table 1. The three of them are early barred spirals and show a high star formation rate in their nuclear regions. They are quoted in the literature as among the spirals with the highest overall oxygen abundances (Zaritsky, Kennicutt & Huchra 1994; Pérez-Olea 1996).

NGC 2903 is a well-studied galaxy. The Paschen α image obtained with the Hubble Space Telescope (HST) reveals the presence of a nuclear ring-like morphology with an apparent diameter of approximately 15 arcsec = 625 pc (Alonso-Herrero, Ryder & Knapen 2001). This structure is also seen, though less prominent, in the Hα observations from Planesas, Colina & Perez-Olea (1997). A large number of stellar clusters are identified on high-resolution infrared images in the K' and H bands, which do not coincide spatially with the bright H II regions. A possible interpretation of this is that the stellar clusters are the result of the evolution of giant H II regions (e.g. Alonso-Herrero et al. 2001). The global star formation rates in the nuclear ring, as derived from its Hα luminosity is found to be $0.1 M_\odot$ yr$^{-1}$ by Planesas et al. (1997) and $0.7 M_\odot$ yr$^{-1}$ from Alonso-Herrero et al. (2001). From CO emission observations, Planesas et al. (1997) derive a mass of molecular gas (H$_2$) of $1.8\times 10^8 M_\odot$ inside a circle 1 kpc in diameter.

NGC 3351 is another well known ‘hotspot’ galaxy (Sérsic & Pastoriza 1967). Early detailed studies of its nuclear regions (Alloin & Nieto 1982) concluded that NGC 3351 harbours high mass circumnuclear star formation. In fact, the star formation rate per unit area in the nuclear region is significantly increased over that observed in the disc (Devereux, Kenney & Young 1992). Elmegreen et al. (1997) from near-infrared (IR) photometry in the $J$ and $K$ bands derive a circumnuclear star formation rate of 0.38 $M_\odot$ yr$^{-1}$. Planesas et al. (1997), from the Hα emission, derive a total star formation rate for the circumnuclear region of 0.24 $M_\odot$ yr$^{-1}$ and a mass of molecular gas of $3.5\times 10^8 M_\odot$ inside a circle of 1.4 kpc in diameter, from CO emission observations. A recent kinematical study of the CNSFR has been presented in Hägele et al. (2007a).

NGC 3504 is the brightest galaxy in the optically selected catalogue of starburst galactic nuclei in Balzano (1983). It forms a pair with NGC 3512. Various studies at different wavelengths confirmed that it harbours a very intense nuclear starburst (Devereux 1989; Puxley, Hawarden & Mountain 1990). Infrared observations in the $J$ and $K$ bands reveal a ring with five discrete clumps of star formation with colours indicating ages of about 10$^7$ yr (Elmegreen et al. 1997). The Hα emission from Planesas et al. (1997) traces a
compact ring structure with a radius of 2 arcsec (200 pc) around the nucleus where four separated H II regions can be identified. From the Hα emission, these authors derived a global star formation rate for the circumnuclear region of $0.62 \pm 0.10 \ M_\odot \ yr^{-1}$, while from their CO observations, a molecular gas mass of $2 \times 10^8 \ M_\odot$ inside a circle 2.7 kpc in diameter is derived.

### 3 OBSERVATIONS AND DATA REDUCTION

Our spectrophotometric observations were obtained with the 4.2-m William Herschel Telescope (WHT) at the Roque de los Muchachos Observatory, in 2001 January 26, using the ISIS (Integrated Science Instrument Server) double spectrograph, with the E2V12 and TEK4 detectors in the blue and red arms, respectively. The incoming light was split by the dichroic at $\lambda 7500$ Å. Gratings R300B in the blue arm and R600R in the red arm were used, covering 3400 Å in the blue ($\lambda 3650$ to $\lambda 7000$) and 800 Å in the near-IR ($\lambda 8850$ to $\lambda 9650$) and yielding spectral dispersions of 1.73 Å pixel$^{-1}$ in the blue arm and 0.79 Å pixel$^{-1}$ in the red arm. With a slit-width of 1.05 arcsec, spectral resolutions of $\sim 2.0$ and 1.5 Å FWHM (full width at half-maximum) in the blue and red arms, respectively, were attained. This is an optimal configuration which allows the simultaneous observation of a given region in both frames in a single exposure.

The nominal spatial sampling is 0.4 arcsec pixel$^{-1}$ in each frame and the average seeing for this night was $\sim 1.2$ arcsec. A journal of the observations is given in Table 2.

| Galaxy   | Spectral range (Å) | Grating  | Disp. (Å pixel$^{-1}$) | Spatial resolution (arcsec pixel$^{-1}$) | PA (°) | Exposure time (s) |
|----------|--------------------|----------|----------------------|----------------------------------------|-------|------------------|
| NGC 2903 | 3650–7000          | R300B    | 1.73                 | 0.4                                    | 105   | 2 × 1800         |
| NGC 2903 | 8850–9650          | R600R    | 0.79                 | 0.4                                    | 105   | 2 × 1800         |
| NGC 3351 | 3650–7000          | R300B    | 1.73                 | 0.4                                    | 162   | 2 × 1800         |
| NGC 3351 | 8850–9650          | R600R    | 0.79                 | 0.4                                    | 162   | 2 × 1800         |
| NGC 3351 | 3650–7000          | R300B    | 1.73                 | 0.4                                    | 10    | 2 × 1800         |
| NGC 3351 | 8850–9650          | R600R    | 0.79                 | 0.4                                    | 10    | 2 × 1800         |
| NGC 3504 | 3650–7000          | R300B    | 1.73                 | 0.4                                    | 105   | 2 × 1800         |
| NGC 3504 | 8850–9650          | R600R    | 0.79                 | 0.4                                    | 110   | 2 × 1800         |

Regarding background subtraction, the high spectral dispersion used in the near-IR allowed the almost complete elimination of the night-sky OH emission lines and, in fact, the observed $\lambda 9532/9069$ ratio is close to the theoretical value of 2.44 in most cases. Telluric absorptions have been removed from the spectra of the regions by dividing by the relatively featureless continuum of a subdwarf star observed in the same night.

### 4 RESULTS

Fig. 2 shows the spatial distribution of the Hα flux along the slit for the six different positions observed in the sample, a single one in the case of NGC 3504, two in NGC 2903 and three in NGC 3351. The regions that were extracted into one-dimensional spectra are delimited by arrows. The spectra corresponding to each of the identified regions are shown in Figs 3, 4 and 5 for NGC 2903, 3351 and 3504, respectively.

#### 4.1 Underlying population

The presence of underlying Balmer stellar absorptions is clearly evident in the blue spectra of the observed regions (see Figs 3, 4 and 5) and complicates the measurements. A two-component – emission and absorption – Gaussian fit was performed in order to correct the Balmer emission lines for this effect. An example of this procedure can be seen in Fig. 6. The equivalent widths (in Åmstrongs) of the Gaussian absorption components resulting from the fits are given in Table 4 together with the ratio between the line flux measured after subtraction of the absorption component and the line flux measured without any correction and using a pseudo-continuum placed at the bottom of the line. This factor provides a
Figure 1. Observed CNSFR in each of the galaxies. The different slit positions are superimposed on images taken from the HST archive and obtained with the WFPC2 camera through the F606W filter. The position angles (PAs) of every slit position are indicated.

Table 3. Characteristics of the CNSFR observed.

| Galaxy   | Region | Offsets from centre (arcsec) | Diameter$^a$ (arcsec) | $P$(Hα) ($\times 10^{-14}$ erg s$^{-1}$ cm$^{-2}$) |
|----------|--------|-----------------------------|-----------------------|------------------|

|          | R3     | $-1.6, -0.3$                | 2.0                   | 2.6              |
|          | R4     | $-0.3, -3.3$                | 2.4                   | 10.1             |
|          | R6     | $+2.3, +2.4$                | 2.4                   | 12.7             |
|          | R7     | $+4.8, +3.6$                | 1.8                   | 9.5              |
| NGC 3351 | R1     | $+0.4, +6.5$                | 2.4                   | 12.3             |
|          | R2     | $-2.6, +2.6$                | 2.4                   | 16.0             |
|          | R3     | $-1.5, -6.5$                | 2.4                   | 20.7             |
|          | R4     | $+0.5, 5.4$                 | 2.2                   | 10.5             |
|          | R5     | $+2.9, -3.5$                | 2.4                   | 4.9              |
|          | R6     | $+4.1, -0.4$                | 2.4                   | 6.1              |
|          | R7     | $+4.8, +3.6$                | 1.8                   | 9.5              |
| NGC 3504 | R3+R4  | $-0.5, -1.7$                | 1.6                   | 21.6             |

$^a$Size of the circular aperture used to measure fluxes.

value for the final correction to the measured fluxes in terms of each line flux. In regions R4 of NGC 2903 and R5 of NGC 3351 the Hα line is seen only in absorption. In region R5 of NGC 3351 also Hγ is seen only in absorption. No fitting was performed for these lines, hence no correction is listed for them in Table 4. In the case of the He I and Paschen no prominent absorption line wings are observed that allow the fitting of an absorption component as it was done in the case of the Balmer lines. These lines were measured with respect to a local continuum placed at their base, which partially corrects by underlying absorption.

4.2 Line intensity measurements

Emission-line fluxes were measured on the extracted spectra using the IRAF SPLT software package, by integrating the line intensity over a local fitted continuum. The errors in the observed line fluxes

have been calculated from the expression \( \sigma_l = \sigma_c N^{1/2} \left[ 1 + \frac{\text{EW}}{(N\Delta)} \right]^{1/2} \), where \( \sigma_l \) is the error in the line flux, \( \sigma_c \) represents the standard deviation in a box near the measured emission line and stands for the error in the continuum placement, \( N \) is the number of pixels used in the measurement of the line flux, EW is the line equivalent width and \( \Delta \) is the wavelength dispersion in Ångstroms per pixel. The first term represents the error in the line flux introduced by the uncertainty in the placement of the continuum, while the second one scales the signal-to-noise ratio in the continuum to the line (Gonzalez-Delgado et al. 1994).

The Balmer emission lines were corrected for the underlying absorption as explained above. Then the logarithmic extinction at Hβ, c(Hβ) was calculated from the Balmer line decrements assuming the Balmer line theoretical values for case B recombination (Brocklehurst 1971) for a temperature of 6000 K, as expected for high metallicity regions, and an average extinction law (Miller & Mathews 1972). An example of this procedure is shown in Fig. 7 for region R1+R2 of NGC 2903, where the logarithm of the quotient between observed and theoretical Balmer decrements is represented against the logarithmic extinction at the Balmer line wavelengths, f(λ). The tight relation found for a baseline from the Paschen lines to Hδ can be taken as evidence of the reliability of our subtraction procedure for this region. This is also the case for most regions, although in some cases the Hγ/Hβ ratio lies above or below the reddening line, implying that the subtraction procedure is not that good for this line. This is not surprising since the presence of the G band and other metal features in the left wing of the line, makes the fitting less reliable than for the other Balmer lines. We have used all the available Balmer and Paschen-to-Balmer ratios, although due to the uncertainties in the emission line intensities of the higher
order Balmer lines, which are difficult to estimate (in fact, in some regions they are seen only in absorption), these ratios have been given a lower weight in the fit. This almost amounts to deriving the values of $c$(H$\beta$) from the H$\alpha$/H$\beta$ ratio and checking for consistency against the values measured for the Paschen lines, which are much less affected by underlying absorption due the smaller contribution to the continuum from main sequence AF stars. The errors in $c$(H$\beta$) have in fact been derived from the measured errors in the H$\alpha$ and
Hβ lines, since in any weighted average these two lines have by far the largest weight.

The blue region of the spectrum near the Balmer discontinuity is dominated by absorption lines which cause a depression of the continuum and difficult the measurement of the [O II] lines at λ3727 Å. None of them however is at the actual wavelength of the [O II] line. This can be seen in Fig. 8 where we show the spectrum of region R1+R2 in NGC 2903 compared to that corresponding to a globular
Figure 4 – continued

Abundances of circumnuclear star-forming regions

5 CHEMICAL ABUNDANCES

Electron densities for each observed region have been derived from the [S ii] \(\lambda\lambda 6717, 6731\) Å line ratio, following standard methods (e.g. Osterbrock 1989). They were found to be, in all cases, \(\leq 600\) cm\(^{-3}\), higher than those usually derived in disc H II regions, but still below the critical value for collisional de-excitation.

The low excitation of the regions, as evidenced by the weakness of the [O iii] \(\lambda 5007\) Å line (see left-hand panels of Figs 3, 4 and 5), precludes the detection and measurement of the auroral [O iii] \(\lambda 4363\) Å necessary for the derivation of the electron temperature. It is therefore impossible to obtain a direct determination of the oxygen abundances. Empirical calibrations have to be used instead.

Different calibrators for strong emission lines have been proposed in the literature for different kinds of objects involving different chemical elements, among others, the oxygen abundance parameter \(R_{23} \equiv O_{23}\) (Pagel et al. 1979), the nitrogen N2

Table 4. Equivalent widths of Balmer absorption lines for the observed CNSFR.

| Galaxy   | Region | \(H\beta\) (Å) | Corr. factor | \(H\gamma\) (Å) | Corr. factor | \(H\beta\) (Å) | Corr. factor |

This makes possible for the first time to calibrate the elemental (ionization parameter) effects. The amount of available data on sulphur emission lines is growing, especially in the high metallicity regime. This makes possible for the first time to calibrate the electron temperature of [S iii] in terms of the SO$_{23}$ parameter. To perform this calibration we have compiled all the data so far at hand with sulphur emission-line data both for the auroral and nebular lines at 6312 Å and λ9069, 9532 Å respectively. The sample comprises data on galactic (García-Rojas 2006) and extragalactic (Díaz et al. 1987; Vilchez et al. 1988; Pastoriza et al. 1993; Gonzalez-Delgado et al. 1994; González-Delgado et al. 1995; Garnett et al. 1997; Díaz et al. 2000; Castellanos, Díaz & Terlevich 2002; Kennicutt, Bresolin & Garnett 2003; Bresolin, Garnett & Kennicutt 2004; Bresolin et al. 2005) H II regions and H II galaxies (Skillman & Kennicutt 1993; Skillman et al. 1994; Pérez-Montero & Díaz 2003; Hägele et al. 2006b). The data on extragalactic H II regions has been further split into low and high metallicity H II regions according to the criterion of Díaz & Pérez-Montero (2000), i.e. log O$_{32}$ < 0.47 and −0.5 ≤ log S$_{23}$ ≤ 0.28 implies oversolar abundances. For all the regions the [S iii] electron temperature has been derived from the ratio between the auroral and the nebular sulphur lines, using a five-level atom program (Shaw & Dufour 1995) and the collisional strengths from Tayal & Gupta (1999), through the task TEMDEN as implemented in the IRAF package. The calibration is shown in Fig. 9 together with the quadratic fit to the high metallicity H II region data:

\[ t_e([S	ext{iii}]) = 0.596 - 0.283 \log \text{SO}_{23} + 0.199(\log \text{SO}_{23})^2. \]

Fig. 10 shows the comparison between the electron temperatures and ionic sulphur abundances derived from measurements of the auroral sulphur line 6312 Å and our derived calibration. The S$^+$/H$^+$ and S$^{2+}$/H$^+$ ionic ratios have been derived from

\[ 12 + \log \frac{S^+}{H^+} = \log \left( \frac{I(6717) + I(6731)}{I(H\beta)} \right) + 5.423 + \frac{0.929}{T} - 0.28 \log t_e. \]
These expressions have been derived by performing appropriate fittings to the ionization task results following the functional form given in Pagel et al. (1992). The assumption has been made that $T_e([\text{S III}]) \approx T_e([\text{O III}])$ in the observed regions. This assumption seems to be justified in view of the results presented by Bresolin et al. (2005).

We have used the calibration above to derive $t_e([\text{S III}])$ for our observed CNSFR. In all cases the values of $\log \text{O}_23$ are inside the range used in performing the calibration, thus requiring no extrapolation of the fit. These temperatures, in turn, have been used to derive the $S^+/H^+$ and $S^{1}/H^+$ ionic ratios. The derived $T_e$ and ionic abundances for sulphur are given in Table 8, together with measured values of the electron density. Temperature and abundance errors are formal errors calculated from the measured line intensity errors applying error propagation formulae, without assigning any error to the temperature calibration itself.

Once the sulphur ionic abundances have been derived, we have estimated the corresponding oxygen abundances. In order to do that, we have assumed that sulphur and oxygen electron temperatures follow the relation given by Garnett (1992) and confirmed by more recent data (Hägele et al. 2006), and hence we have derived $t_e([\text{O III}])$ according to the expression

$$t_e([\text{O III}]) = 1.205 t_e([\text{S III}]) - 0.205.$$

We have also assumed that $t_e([\text{O I}]) \approx t_e([\text{S III}])$. The values of $T_e([\text{O III}])$ and the ionic abundances for oxygen are given in Table 9. The same comments regarding errors mentioned above apply. Finally, we have derived the $N^+$/O$^+$ ratio assuming that $t_e([\text{O I}]) \approx t_e([\text{S III}]) \approx t_e([\text{N III}])$. These values are also listed in Table 9.

For one of the observed regions, R1+R2 in NGC 2903, the [S III] $\lambda 6312 \text{ Å}$ has been detected and measured. Although the line intensity ratios for this region presented in Table 5 have been measured on the combined spectrum of slit positions 1 and 2, the placement of the continuum for the [S III] 6312 line was very uncertain. Therefore, we have performed the temperature measurement on the spectrum extracted from slit position 1, which shows the best-defined continuum. On this spectrum we have measured the intensity of the [S III] $\lambda 6312 \text{ Å}$ line with respect to $H\alpha$, and those of [S III] $\lambda \lambda 9069, 9532 \text{ Å}$ with respect to $\lambda 9$ and $\lambda 9329$, in order to minimize reddening corrections. The region of this spectrum around the [S III] $\lambda 6312 \text{ Å}$ line is shown in Fig. 11 where the horizontal lines show the different placements of the continuum used to measure the line and calculate the corresponding errors. The obtained [S III] nebular to auroral line ratio is 79.4 $\pm$ 49.1 which gives a $T_e([\text{S III}]) = 8400^{+1250}_{-205}$ K, slightly higher than predicted by the proposed fit. This region is represented as a solid black circle in Fig. 9.

### 6 DISCUSSION

#### 6.1 Characteristics of the observed CNSFR

Planesas et al. (1997) provide $H\alpha$ fluxes (from images) for all our observed regions. These values are larger than those measured inside our slit by factors between 1.0 and 2.7, depending on the size of the region, something to be expected given the long-slit nature of our observations. We have calculated the $H\alpha$ luminosities for our regions from our observed values, correcting for extinction according to the values found from the spectroscopic analysis. The resulting values are listed in Table 10. These values are larger than the typical ones found for disc H II regions and overlap with those measured in H II galaxies. The region with the largest $H\alpha$ luminosity is R3+R4 in NGC 3504, for which a value of $2.02 \times 10^{49} \text{ erg s}^{-1}$ is measured.

We have derived the number of hydrogen ionizing photons from the extinction corrected $H\alpha$ flux as

$$\log Q(H\alpha) = 0.802 \times 10^{49} \frac{F(H\alpha)}{10^{-17}} \frac{D}{10} \text{ s}^{-1},$$

where $F(H\alpha)$ is in erg cm$^{-2}$ s$^{-1}$ and the distance, $D$, is in Mpc.

The ionization parameter, \(u\), can be estimated from the [S II]/[S III] ratio (Díaz et al. 1991) as

\[
\log u = -1.68 \log ([S\ II]) / ([S\ III]) - 2.99,
\]

and ranges between −3.12 and −3.98 for our observed CNSFR, in the low side of what is found in disc H II regions, even in the cases of high metallicity (see Díaz et al. 1991).

From the calculated values of the number of Lyman \(\alpha\) photons, \(Q(H\alpha)\), ionization parameter and electron density, it is possible to derive the size of the emitting regions as well as the filling factor (see Castellanos et al. 2002). The derived sizes are between 1.5 arcsec for region R3 in NGC 3351 and 5.7 arcsec for region R4 in NGC 2903; these values correspond to linear dimensions between 74 and 234 pc. The derived filling factors are low: between \(6 \times 10^{-4}\) and \(1 \times 10^{-3}\), lower than commonly found in giant H II regions (∼0.01). Sizes in arcsec, filling factors and the corresponding masses of ionized hydrogen, \(M(H\ II)\), are given in Table 10.

We have also derived the mass of ionizing stars, \(M^*\), from the calculated number of hydrogen ionizing photons with the use of evolutionary models of ionizing clusters (García Vargas & Díaz 1994; Stasińska & Leitherer 1996) assuming that the regions are ionization bound and that no photons are absorbed by dust. A Salpeter initial
mass function (IMF) with upper and lower mass limits of 100 and 0.8 $M_\odot$, respectively, has been assumed. According to these models, a relation exists between the degree of evolution of the cluster, as represented by its Hβ emission line equivalent width and the number of hydrogen ionizing photons per unit solar mass (Díaz 1998; Díaz et al. 2000). The ionizing cluster masses thus derived are given in Table 10 and range between $1.1 \times 10^5$ and $4.7 \times 10^6$ $M_\odot$. The measured Hβ equivalent widths, however, are very low and could be reflecting the contribution by underlying non-ionizing populations.

An alternative way to take into account the cluster evolution in the derivation of the mass is to make use of the existing relation between the ionization parameter and the Hβ equivalent width for ionized regions (Hoyos & Díaz 2006). In that case, the derived masses are lower by factors between 1.5 and 15. At any rate, given the assumptions of no dust absorption or photon leakage, these masses represent lower limits.

6.2 Metallicity estimates

The abundances we derive using our $T_e([\text{S III}])$ calibration are comparable to those found by Bresolin et al. (2004) for their sample of high metallicity H II regions. Most of our CNSFR show total oxygen abundances, taken to be O/H = $O^+$/H$^+$ + $O^+$/H$^+$, consistent with solar values within the errors. The region with the highest oxygen abundance is R3+R4 in NGC 3504: $12+\log(O/H) = 8.85$, about 1.5 solar if the solar oxygen abundance is set at the value derived by Asplund, Grevesse & Sauval (2005), $12 + \log(O/H)_\odot = 8.66 \pm 0.05$. Region R6 in NGC 3351 has the lowest oxygen abundance of the sample, about 0.6 times solar. In all the observed CNSFR the O/H abundance is dominated by the $O^+$/H$^+$ contribution with $0.18 \leq \log(O^+$/O$^+^2) < 0.85$. This is also the case for high metallicity disc H II regions where these values are even higher. For our observed regions, also the $S^+$/S$^2+$ ratios are larger than one, which is at odds with the high metallicity disc H II regions for which, in general, the sulphur abundances are dominated by $S^2+$/H$^+$.

The fact that both O/H and S/H seem to be dominated by the lower ionization species, can raise concern about our method of abundance derivation, based on the calibration of the $T_e([\text{S III}])$. In a recent article Pilyugin (2007) addresses this particular problem. He proposes a calibration of the ratio of the [NII] nebular-to-auroral line intensities in terms of those of the nebular oxygen lines. Then the [NII] electron temperature, thought to properly characterize the low ionization zone of the nebula, can be obtained. We have applied Pilyugin (2007) to our observed CNSFR as well as the high metallicity H II sample. Fig. 12 shows the derived $T_e([\text{N II}])$ following Pilyugin's method against the $T_e([\text{S III}])$ derived from our calibration. The (red) dashed line shows the one-to-one relation while the (black) solid line shows the actual fit to all the data. It can be seen that, in what regards CNSFR, both temperatures are very similar, with the [NII] temperature being, in average, 500 K higher than that of [S III]. This difference is of the same size of the average errors in the measured temperatures entering the calibrations, therefore, we can assume that our derived $T_e([\text{S III}])$ characterizes the low ionization zone at least as well as the $T_e([\text{N II}])$ derived applying Pilyugin's method.

### Table 10. General properties of the observed CNSFR.

| Galaxy   | Region | $F(H\alpha)$ (erg cm$^{-2}$ s$^{-1}$) | $L(H\alpha)$ (erg s$^{-1}$) | $Q(\text{H}^0)$ (photons s$^{-1}$) | $\log u$ | Diameter (arcsec) | $\epsilon$ | $M^*$ ($M_\odot$) | $M(H\alpha)$ ($M_\odot$) |
|----------|--------|--------------------------------------|----------------------------|----------------------------------|----------|------------------|------------|----------------|------------------|

| NGC 3504 | R3+R4  | 4.20E-13                             | 2.02E+40                   | 1.47E+52                         | -3.32    | 3.11             | 6.76E-04  | 4.70E+06        | 8.07E+04        |
Concerning relative abundances, with our analysis it is possible to derive the relative N/O value, assumed to be equal to the $N^{+}/O^{+}$ ratio. These values are in all cases larger than the solar one ($\log(N/O)/\odot = -0.88$; Asplund et al. 2005) by factors between 1.7 (R3+R4 in NGC 3504) and 4.5 (R2 in NGC 3351) which are amongst the highest observed N/O ratios (see e.g. Mollá et al. 2006). Regarding S, if – given the low excitation of the observed regions – the fraction of $S^{3+}$ is assumed to be negligible, the S/O ratio can be obtained as

$$\frac{S}{O} = \frac{S^{+} + S^{2+}}{O^{+} + O^{2+}}.$$ 

The values of $\log(S/O)$ span a very narrow range between $-1.76$ and $-1.63$, that is between 0.6 and 0.8 of the solar value $\log(S/O)/\odot = -1.52$ (Asplund et al. 2005).

6.3 Comparison with high metallicity H II regions

The observed CNSFR being of high metallicity show however marked differences with respect to high metallicity disc H II regions. Even though their derived oxygen and sulphur abundances are similar, they show values of the $O_{23}$ and the N2 parameters whose distributions are shifted to lower and higher values, respectively, with respect to the high metallicity disc sample (Fig. 13). Hence, if pure empirical methods were used to estimate the oxygen abundances for these regions, higher values would in principle be obtained. This would seem to be in agreement with the fact that CNSFR, when compared to the disc high metallicity regions, show the highest $[N\, ii]/[O\, ii]$ ratios. Fig. 14 shows indeed a bi-modal distribution of the $[N\, ii]/[O\, ii]$ ratio in disc and circumnuclear H II regions.

A good correlation has been found to exist between the $[N\, ii]/[O\, ii]$ ratio and the $N^{+}/O^{+}$ ionic abundance ratio, which in turn can be assumed to trace the N/O ratio (Pérez-Montero & Díaz 2005). This relation is shown in Fig. 15 for the observed CNSFR (black circles) and the high metallicity H II region sample (grey circles). The CNSFR sample has been enlarged with two circumnuclear regions of NGC 1097 observed by Phillips et al. (1984) and other three observed in NGC 5953 by Gonzalez Delgado & Perez (1996), all of them of high metallicity. Also shown are data of some CNSFR in two peculiar galaxies: NGC 3310 (Pastoriza et al. 1993) and NGC 7714 (González-Delgado et al. 1995) of reported lower metallicity. In all the cases, ionic and total abundances have been derived following the same methods as in the CNSFR in the present study and described in Section 5. In the case of the latter regions, abundances derived in this way are larger than derived from direct determinations of $T_{e}([O\, iii])$ since our estimated values for this temperature are systematically lower by about 1200 K. This could be due to the fact that our semi-empirical calibration has been actually derived for high metallicity regions. However, the values of $\log(S/O_{23})$ for these regions are between $-0.44$ and $-0.85$ and therefore within the validity range of the calibration and we have preferred to use the same method for consistency reasons.

We can see that a very tight correlation exists which allows to estimate the N/O ratio from the measured $[N\, ii]$ and $[O\, ii]$ emission line intensities. In this relation, high metallicity regions and
CNSFR seem to follow a sequence of increasing N/O ratio. A linear regression fit to the data yields the expression:

$$\log(N/O) = (0.65 \pm 0.02)\log([N\,\text{II}]/[O\,\text{II}]) - (0.79 \pm 0.01).$$

This relation is shallower than that found in Pérez-Montero & Díaz (2005) for a sample that did not include high metallicity H II regions. The N/O ratio for our observed CNSFR is shown in Fig. 16 against their oxygen abundance together with similar data for the high metallicity H II region and H II galaxy samples. It can be seen that all the CNSFR show similar oxygen abundances, with the mean value being lower than that shown by high metallicity disc H II regions, but the observed CNSFR show larger N/O ratios and they do not seem to follow the trend of N/O versus O/H which marks the secondary behaviour of nitrogen.

The values of the oxygen abundance that we find for the CNSFR in NGC 3351 are equal within the errors, with a mean value 12 + log(O/H) = 8.70 ± 0.10, except for region R6 which shows an O/H abundance lower by a factor of about 2. It is worth noting that this is the region with the highest O+/O ratio: 0.83 and a very low O2+/H+ value: 12 + log (O2+/H+) = 7.62 ± 0.17. The average value for the rest of the regions is in agreement with the central abundance found by Pilyugin et al. (2004) by extrapolating the galaxy oxygen abundance gradient, 12 + log(O/H) = 8.74 ± 0.02. This value is somewhat lower than that previously estimated by Vilchez & Contini (2004): 8.90 from the same data but following a different method of analysis. In that same work, the quoted central abundance for NGC 2903 is 12 + log(O/H) = 8.94.

Our results for regions R1+R2, R3 and R6 in this galaxy yield an average value of 8.75 ± 0.09 lower than theirs by 0.2 dex. Region R4 shows a lower oxygen abundance but still consistent within the errors with the average. Values of N/O ratios for the centres of NGC 3351 and NGC 2903 similar to those found here (−0.33 and −0.35, respectively) are quoted by Pilyugin et al. (2004).

Another difference between the high metallicity circumnuclear and disc regions is related to their average ionization parameter. The left-hand panel of Fig. 17 shows the distribution of the [S II]/[S III] ratio for the two samples. The [S II]/[S III] ratio has been shown to be a good ionization parameter indicator for moderate to high metallicities (Díaz et al. 1991) with very little dependence on metallicity or ionization temperature. It can be seen that all the CNSFR observed show large [S II]/[S III] ratios which imply extremely low ionization parameters. On the other hand, a different answer would be found if the [O II]/[O III] parameter, also commonly used as ionization parameter indicator, was used. In this case, CNSFR and high metallicity H II regions show a much more similar distribution, with CNSFR showing slightly lower values of [O II]/[O III] (Fig. 17, right-hand panel).

It should be noted the dependence of the [O II]/[O III] parameter on metallicity due to the presence of opacity edges of various abundant elements (O+, Ne+, C2+, N2+) in the stellar atmospheres that can combine to substantially modify the stellar flux of high abundance stars at energies higher than 35–30 eV and then produce a lower [O II] emission (Balick & Sneyd 1976). However, if the CNSFR were ionized by stars of a higher metallicity than those in disc H II regions this effect would go in the direction of producing higher [O II]/[O III] ratios for the CNSFR, and ionization parameters derived from [O II]/[O III] ratios would be found to be lower than those derived from [S II]/[S III] ratios, contrary to what is actually observed.

The ionization structure can provide important information about the characteristics of the ionizing source. A diagram of the emission line ratios [O II]/[O III] versus [S II]/[S III], in particular, works as a diagnostics for the nature and temperature of the radiation field. This diagram was used in Díaz, Pagel & Wilson (1985) in order to investigate the possible contributions by shocks in CNSFR and LINERs and is the basis of the definition of the $\eta'$ parameter (Vilchez & Pagel 1988). The $\eta'$ parameter defined as

$$\eta' = \frac{[O\,\text{II}]\lambda\lambda3727, 3729/[O\,\text{III}]\lambda4959, 5007}{[S\,\text{II}]\lambda\lambda6716, 6731/[S\,\text{III}]\lambda\lambda9069, 9532}$$

is a measure of the ‘softness’ of the ionizing radiation and increases with decreasing ionizing temperature. The ‘$\eta'$ plot’ is shown in

Figure 16. Relation between the N/O ratio and the O/H abundance for CNSFR (black circles and green upside down triangles for high and low metallicities, respectively), high metallicity H II regions (grey circles) and H II galaxies (cyan diamonds).

Figure 17. Distribution of the [S II]/[S III] (left) and [O II]/[O III] (right) ratios for the observed CNSFR (criss-crossed) and the sample of high metallicity disc H II regions (hatched).
while the latter cluster around log $sulphur$ ionic and total abundances would be decreased by about a factor of 2 would decrease the SO $23$ parameter by a factor between 1.5 and 1.8 depending on the region, which would lead to increased $[S\,ii]$ electron temperatures by between 500 and 1000 K. The corresponding $O^+/H^+$ would be only slightly smaller, by about 0.10 dex, as would also be the total O/H abundances which is dominated by $O^+/H^+$. The $O^{2+}/H^+$ ionic ratio however would be lower by between 0.3 and 0.4 dex, which would produce an ionization structure more similar to what is found in disc H II regions. The sulphur ionic and total abundances would be decreased by about 0.17 dex. Finally, the $N^+/O^+$ ratios would be decreased by about 0.17 dex, while the $S/O$ ratios would remain almost unchanged. In the '$n'$ plot (Fig. 18) the data points corresponding to our observed CNSFR would move upwards by 0.30 dex. However, we do not find any compelling reason why the $[O\,ii]$ intensities should be larger than measured by such a big amount (see Section 4.2 and Fig. 8).

A final remark concerns the gas kinematics in CNSFR. In a recent work Hägele et al. (2007a) have studied the kinematics of gas and stars in the CNSFR of NGC 3351 finding two different components for the ionized gas in $H\beta$ and $[O\,ii]$ emission: a ‘broad component’ with a velocity dispersion similar to that measured for the stars, and a ‘narrow component’ with a dispersion lower than the stellar one by about 30 km s$^{-1}$. Obviously the abundance analysis and the location of these regions on diagnostic diagrams would be affected if more than one velocity component in the ionized gas corresponding to kinematically distinct systems are present.
7 SUMMARY AND CONCLUSIONS

We have obtained spectrophotometric observations in the optical ($\lambda\lambda\lambda\lambda 3650–7000$ Å) and far-red ($\lambda\lambda\lambda\lambda 8850–9650$ Å) wavelength ranges of 12 circumnuclear H II regions in the early-type spiral galaxies: NGC 2903, 3351 and 3504. These regions were expected to be amongst the highest metallicity regions as corresponds to their position near the galactic centre. At the same time, this position implies a substantial contribution by the bulge stellar population to their spectra which represents a major observational problem and compromises the reliability of the emission-line intensities. Its proper subtraction however requires the detailed modelling of the stellar population and the disentangling of the contribution by the bulge and by any previous stellar generations in the CNSFR themselves. Almost all these regions show the presence of the CaT lines in the far-red (see Hägele et al. 2007a) some of them with equivalent widths that suggest a certain contribution by red supergiant stars. A detailed study of the ionizing and non-ionizing stellar populations of this region will be presented in a forthcoming paper. In the case of the Balmer lines, the presence of wide wings in their profiles, allows to perform a two-component – emission and absorption – Gaussian fit in order to correct the Balmer emission lines for this effect.

We have derived the characteristics of the observed CNSFR in terms of size, H$\alpha$ luminosities and ionizing cluster masses. The derived sizes are between 1.5 and 5.7 arcsec which correspond to linear dimensions between 74 and 234 pc. The derived filling factors, between $6 \times 10^{-4}$ and $1 \times 10^{-3}$, are lower than commonly found in giant H II regions ($\sim 0.01$). H$\alpha$ luminosities are larger than the typical ones found for disc H II regions and overlap with those measured in H II galaxies. The region with the largest H$\alpha$ luminosity is R3+R4 in NGC 3504, for which a value of $2.02 \times 10^{40}$ is measured. Ionizing cluster masses range between $1.1 \times 10^5$ and $4.7 \times 10^5 M_{\odot}$ but could be lower by factors between 1.5 and 15 if the contribution by the underlying stellar population is taken into account.

The low excitation of the regions, as evidenced by the weakness of the [O III] $\lambda\lambda\lambda\lambda 4363$ Å necessary for the derivation of the electron temperature. Only for one of the regions, the [S III] $\lambda\lambda\lambda\lambda 6312$ Å line was detected providing, together with the nebular [S III] lines at $\lambda\lambda\lambda\lambda 9532$ Å a value of the electron temperature of $T_e([S\;\text{iii}]) = 8400^{\pm 1250}$ K. A new method for the derivation of sulphur abundances was developed based on the calibration of the [S III] electron temperature versus the empirical parameter SO$_{23}$ defined as the quotient of the oxygen and sulphur abundance parameters O$_{23}$ and S$_{23}$ and the further assumption that $T([S\;\text{iii}]) \simeq T([S\;\text{ii}])$. Then the oxygen abundances and the N/O and S/O ratios can also be derived.

The derived oxygen abundances are comparable to those found in high metallicity disc H II regions from direct measurements of electron temperatures and consistent with solar values within the errors. The region with the highest oxygen abundance is R3+R4 in NGC 3504, $12 + \log(O/H) = 8.85$, about 1.5 solar if the solar oxygen abundance is set at the value derived by Asplund et al. (2005), $12 + \log(O/H)_0 = 8.66 \pm 0.05$. Region R7 in NGC 3515 has the lowest oxygen abundance of the sample, about 0.6 times solar. In all the observed CNSFR the O/H abundance is dominated by the O$^+$/H$^+$ contribution, as is also the case for high metallicity disc H II regions. For our observed regions, however, also the S$^+/S^{2+}$ ratio is larger than one, different from the case of high metallicity disc H II regions for which, in general, the sulphur abundances are dominated by S$^{2+}$/H$^+$. The derived N/O ratios are in average larger than those found in high metallicity disc H II regions and they do not seem to follow the trend of N/O versus O/H which marks the secondary behaviour of nitrogen. On the other hand, the S/O ratios span a very narrow range between 0.6 and 0.8 of the solar value.

When compared to high metallicity disc H II regions, CNSFR show values of the O$_{23}$ and the N2 parameters whose distributions are shifted to lower and higher values, respectively, hence, even though their derived oxygen and sulphur abundances are similar, higher values would in principle be obtained for the CNSFR if pure empirical methods were used to estimate abundances. CNSFR also show lower ionization parameters than their disc counterparts, as derived from the [S III]/[S III] ratio. Their ionization structure also seems to be different with CNSFR showing radiation field properties more similar to H II galaxies than to disc high metallicity H II regions. The possible contamination of their spectra from hidden low luminosity AGN and/or shocks, as well as the probable presence of more than one velocity component in the ionized gas corresponding to kinematically distinct systems, should be further investigated.

ACKNOWLEDGMENTS

The WHT is operated in the island of La Palma by the Isaac Newton Group in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias. We thank the Spanish allocation committee (CAT) for awarding observing time. This work has been partially supported by DGICYT grant AYA-2004-02860-C03. GH acknowledges support from the Spanish MEC through FPU grant AP2003-1821. AID acknowledges support from the Spanish MEC through a sabbatical grant PR2006-0049. Also, partial support from the Comunidad de Madrid under grant S-0505/ESP/000237 (ASTROCAM) is acknowledged. Support from the Mexican Research Council (CONACYT) through grant 49942 is acknowledged by ET. We thank the hospitality of the Institute of Astronomy, Cambridge, where most of this paper was written.

We would like to thank Mike Beasley for providing the digital spectrum of the M31 cluster, Roberto Cid Fernandes for very helpful discussions concerning subtraction procedures of the underlying absorptions and Roberto Terlevich for a careful reading of this manuscript. We also thank an anonymous referee for a very careful review of this work which leads to the improvement of the paper. This work is dedicated to the memory of Bernard Pagel who was always a source of inspiration and stimuli for us and with whom we discussed many of the matters addressed in this paper over the last twenty years or so.
