ABSTRACT

Most root canal procedures are anatomically complex, resulting in insufficient removal of the necrotic pulp by mechanical root canal shaping. This study evaluated the use of antibiotics as canal irrigants for removal of susceptible intracanal bacteria, using an *Enterococcus faecalis* biofilm model. *Enterococcus faecalis* biofilm was developed in the root canal and test tube. For the experiments, sodium hypochlorite (NaOCl), augmentin and erythromycin were used as intracanal irrigants. The test tubes and canals were prepared and irrigated with phosphate buffered saline (PBS), NaOCl, augmentin and erythromycin. Bacterial samples were collected after irrigation in the test tube models on day 1, and from the tooth model on days 1, 4 and 7. The surface of each sample and attached pattern of the bacteria was also analyzed by examining under scanning electron microscopy (SEM). The antibacterial study using 10 ml test tubes (n=10) revealed that 5% NaOCl, augmentin and erythromycin inhibited bacterial growth relative to PBS. In the tooth model, NaOCl, augmentin and erythromycin inhibited bacterial growth significantly (all p<0.05) at days 4 and 7, relative to PBS. Compared to day 1, bacterial density of all groups reduced at day 7, and changes in cell morphology were observed in all experimental groups. Our studies revealed evidence of significant differences in the antimicrobial efficacy at days 4 and 7, upon irrigation with augmentin and erythromycin versus PBS, in root canals infected with *E. faecalis*.

KEY WORDS: Augmentin, Biofilm, Canal irrigation, *Enterococcus faecalis*, Erythromycin

Introduction

The main purpose of root canal therapy is to remove dental pulp, remaining dentin and microorganisms from the root canal system. Most of the root canal is anatomically complex, which leads to an insufficiency in removing the entire necrotic pulp by mechanical root canal shaping. Thus, it is necessary to use intracanal irrigants in the middle of a mechanical root canal shaping procedure. Currently, sodium hypochlorite (NaOCl) is the most popular irrigant in root canal therapy. NaOCl effectively removes organic tissue and virus. NaOCl has strong antimicrobial activity. Its use combined with instrumentation removes the majority of the microbial cells in the root canal. However, a small portion of the flora survives [1].

*Enterococcus faecalis* is a facultative anaerobic gram-positive coccus and is the most common *Enterococcus* species cultured from non-healing endodontic cases. It persists in treated root canals [2-5]. *E. faecalis* has been suggested as the main cause for endodontic failure. With its resistance to intracanal medicaments and even to pH 11.5 environments, *E. faecalis* is able to tolerate calcium hydroxide antimicrobial treatment [6]. As it can also tolerate persistent nutrient starvation, *E. faecalis* can survive more than 4 weeks after canal filling, and proliferates as a single infection type without the presence of other bacteria.

Various methods for the elimination of *E. faecalis* have been studied. These include the use of various instru-
Antibiotics for bacteria removal

ments, intracanal irrigant regimens, intracanal medica-
ments, and local application of antibiotics within the root
canal system. *E. faecalis* is resistant to multiple anti-
microbial agents, so the selection and use of the appropriate
local antibiotics to the persistent endodontic infections is
challenging [7].

Resistance of *E. faecalis* is caused by formation of a
biofilm that harbors multiple bacteria in an intracanal
polysaccharide matrix [8]. The biofilm mode of growth
confers antibiotic resistance [9,10] and can protect the
bacteria from defense mechanisms of the immune system.
When *E. faecalis* grows as a biofilm, the genetic and met-
abolic transformations in the adherent bacteria prevent the
penetration and action of several antimicrobial agents [11].
*E. faecalis* that invades the dentinal tubules may survive in
chemomechanical instrumentation and intracanal medica-
tion [12], and can colonize tubules and reinfect the obtu-
rated root canals [13].

Augmentin contains a combination of amoxicillin and
clavulanate potassium. Amoxicillin is a penicillin antibi-
otic. Clavulanate potassium is a form of clavulanic acid
similar to penicillin. Augmentin is used to treat many dif-
ferent infections caused by bacteria, such as sinusitis,
pneumonia, ear infections, bronchitis, urinary tract infec-
tions, and infections of the skin. Erythromycin is a that has
an antimicrobial spectrum similar to or slightly wider than
that of penicillin, and is often for people who have an to
penicillin antibiotics.

To increase antibiotic activity to the experimentally formed
*E. faecalis* biofilm, antibiotics were used as intracanal irri-
gants, which in solution could reach to the inaccessible
dentinal tubule. The purpose of this study was to evaluate
the susceptibility of antibiotics as canal irrigants for
removal of intracanal bacteria using an *E. faecalis* biofilm
model.

Materials and Methods

Sample preparation

Single-rooted human teeth with fully formed apices
were used. All teeth were stored in 0.5% thymol solution
at 4°C before use. The crowns were removed and the tooth
length was standardized to 17 mm from the root apex to
the coronal border. Samples were flared using a #4 Gates-
Glidden bur in the coronal third, and then instrumented
using the crown-down technique and rotary instruments
(BLX Ni-Ti file; B&L Biotech, Seoul, Korea). Following
preparation, each tooth was irrigated with 5 ml of 5%
NaOClI, followed by 5 ml of saline to remove the smear
layer. Samples were dried with a paper point, fixed to an
Eppendorf tube by an orthodontic acrylic resin (Ortho-Jet,
Lang Dental Manufacturing, Wheeling, IL), and sterilized
for 15 minutes at 121°C.

Biofilm formation and application of the antimicrobial
agents

*E. faecalis* (NCTC 29211) cultures were grown over-
night in Tryptone Soy Broth (TSB) at 37°C. The super-
natant was centrifuged, dissolved in fresh TSB (5 × 10^7
colony forming units (CFU)/ml) and cultured in 10 ml test
tubes for 1 week to prepare tooth sample and test tube.
Samples were cultured in an anaerobic chamber at 37°C in
an environment of 85% N_2, 10% H_2, and 5% CO_2.

After the biofilm-formed root canal was washed twice
using phosphate buffered saline (PBS), it was treated with
PBS, 5% NaOCl, augmentin, and erythromycin for 1, 4,
and 7 days. For the test tube group, all intracanal irrigants
treated for 1 day only. The concentration of the antibiotics
was as previously described [14]. At each step, the root
canal was washed twice by PBS, and the bacteria were
removed by sterilized paper point and dissolved in PBS.
Absorbance of the dissolved bacteria was measured at 600
nm using a spectrophotometer. *E. faecalis* CFU was mea-
sured at intervals during the 48-hour growth on TSB agar.

Scanning electron microscopy (SEM)

Bacterial biofilm development onto root canal dentin
was monitored by SEM examination at 1, 4, and 7 days.
Each group treated with intracanal irrigant was immersed
in 2% gluteraldehyde and 2% paraformaldehyde buffering
with 0.05 M cacodylate buffer (pH 7.2) for 4 hours at 4°C
for fixation, washed three times with 0.05 M cacodylate
buffer (pH 7.2) and then dehydrated in an ascending eth-
anol series (50%, 70%, 90%, 95%, and 100%) for 10 min-
utes each. The samples were treated with t-butylalcohol
for 2 hours at -20°C and then frozen using liquid nitrogen.
The samples were split using a hammer and chisel.
Finally, the samples were dried using a freezing dryer
apparatus (LABCONCO, Kansas City, MO) using liquid
CO_2 replacement. Each sample was mounted and coated
with a 200 Å layer of gold palladium. The canal was
observed by using a S-4700 field-emission scanning elec-
tron microscope (Hitachi, Tokyo, Japan) at 30 kV at days
Statistical analysis

One-way ANOVA was performed to elucidate the effect of each antibiotic. SPSS 18.0 (SPSS, Chicago, IL) was used. Elapsed time and type of antibiotics were assigned as fixed factors, CFU enumeration was assigned as a dependent variable. Additional post-hoc analysis was performed to confirm difference of each group. Significance level was 0.05.

Results

Antibacterial study using 10 ml test tube (n=10) revealed that the 5% NaOCl, augmentin, and erythromycin inhibited bacterial growth relative to PBS (Fig. 1). CFU determinations and SEM analysis of the tooth model (n=9) revealed that NaOCl, augmentin, and erythromycin inhibited bacterial growth significantly \( (p<.05) \) at day 4 and 7 relative to bacteria cultured without intracanal irrigants and to PBS (Table 1). Fig. 2 displays a representative SEM image of bacteria at day 1 and 7. Compared to day 1, bacterial density of all groups reduced at day 7 and morphology was changed in all experimental groups.

Discussion

Persistent endodontic disease after root canal therapy may be caused by bacteria in dentinal tubules [15]. Current mechanical techniques of root canal treatment may leave untreated areas of the root canal system [16]. Mechanical instrumentation without irrigation is insufficient to eliminate bacteria in the canal [17-19]. Therefore, intracanal irrigant is necessary for efficient removal of bacteria.

In this study, the two antibiotics selected have been reported as efficient agents for \( E. \) faecalis [4,5,20,21]. CFU determinations and SEM analysis revealed that NaOCl, augmentin, and erythromycin inhibited bacterial growth significantly \( (p<.05) \) at day 4 and 7 relative to control and PBS. In the case of erythromycin, we used erythromycin standard solution (Sigma-Aldrich, St Louis, MO) in the pilot study. By using this solution, we expected this intracanal irrigant to work more efficiently against \( E. \) faecalis biofilm. However, because the limited solubility that prevented reaching the appropriate concentration, we finally used a powdered form of erythromycin dissolved in ethanol and then filtered. It was possible that the ethanol solvent might have synergistically increased the killing effect of erythromycin on \( E. \) faecalis.

The primary goal of this study was to evaluate the possibility of using antibiotics as an intracanal irrigant, rather than an intracanal medicament. The ideal intracanal irrigant has rapid antibacterial activity, dissolves necrotic tissue, lubricates the canal, removes the smear layer, and does not irritate healthy tissues [22,23]. Therefore, we first performed test tube experiments to define the appropriate application time for eliminating \( E. \) faecalis biofilm. NaOCl, PBS: phosphate buffered saline; Different letter means significant difference.
Antibiotics for bacteria removal

Erythromycin, and augmentin displayed significantly lower absorbance compared to PBS at day 1 (Fig. 1). However, in the tooth model, there were no significant differences among the experimental groups on day 1. The reason might be the complexity of root canal, which is different from the test tube.

NaOCl, erythromycin, and augmentin significantly reduced intracanal bacteria levels compared with the use of PBS.

Fig. 2. Scanning electron microscopy image of bacteria in the tooth model. A. Images acquired at one day. (a) PBS group (top left: 4,000X), (b) NaOCl group (top right: 4,000X), (c) Augmentin group (bottom left: 4,000X), and (d) Erythromycin group (bottom right: 4,000X). B. Images acquired at 7 days. (a) PBS group (top left: 4,000X), (b) NaOCl group (top right: 4,000X), (c) Augmentin group (bottom left: 4,000X), and (d) Erythromycin group (bottom right: 4,000X).
on day 4 and 7. Augmentin showed lower intracanal bacterial levels compared with erythromycin on day 4. However, there was no statistical difference between augmentin and erythromycin. In contrast, the intracanal bacterial level of erythromycin was significantly lower than that of augmentin on day 7 (p < 0.05). The bacterial density of erythromycin was lower than that of augmentin (Fig. 2). As mentioned earlier, the solvent may have had a synergistic effect on elimination of E. faecalis.

In conclusion, the results of this study showed significant differences in the antimicrobial efficacy of irrigating with 1% NaOCl irrigant was most effective method to remove E. faecalis. Also, significant differences were apparent in the antimicrobial efficacy of irrigation with augmentin and erythromycin versus PBS in the root canal infected with E. faecalis on day 4 and 7.
