ABSTRACT

Aims. Ambipolar diffusion can cause a velocity drift between ions and neutrals. This is one of the non-ideal magnetohydrodynamics (MHD) effects proposed to enable the formation of large-scale Keplerian disks with sizes of tens of au. To observationally study ambipolar diffusion in collapsing protostellar envelopes, we compare here gas kinematics traced by ionized and neutral molecular lines and discuss the implication on ambipolar diffusion.

Methods. We analyzed the data of the H13CO+ (3–2) and C18O (2–1) emission in the Class 0 protostar B335 obtained with our ALMA observations. We constructed kinematical models to fit the velocity structures observed in the H13CO+ and C18O emission and to measure the infalling velocities of the ionized and neutral gas on a 100 au scale in B335.

Results. A central compact (~1″–2″) component that is elongated perpendicular to the outflow direction and exhibits a clear velocity gradient along the outflow direction is observed in both lines and most likely traces the infalling flattened envelope. With our kinematical models, the infalling velocities in the H13CO+ and C18O emission are both measured to be 0.85 ± 0.2 km s⁻¹ at a radius of 100 au, suggesting that the velocity drift between the ionized and neutral gas is at most 0.3 km s⁻¹ at a radius of 100 au in B335.

Conclusions. The Hall parameter for H13CO+ is estimated to be ≳1 on a 100 au scale in B335, so that H13CO+ is expected to be attached to the magnetic field. Our non-detection or upper limit of the velocity drift between the ionized and neutral gas could suggest that the magnetic field remains rather well coupled to the bulk neutral material on a 100 au scale in this source, and that any significant field-matter decoupling, if present, likely occurs only on a smaller scale, leading to an accumulation of magnetic flux and thus efficient magnetic braking in the inner envelope. This result is consistent with the expectation from the MHD simulations with a typical ambipolar diffusivity and those without ambipolar diffusion. On the other hand, the high ambipolar drift velocity of 0.5–1.0 km s⁻¹ on a 100 au scale predicted in the MHD simulations with an enhanced ambipolar diffusivity by removing small dust grains, where the minimum grain size is 0.1 μm, is not detected in our observations. However, because of our limited angular resolution, we cannot rule out a significant ambipolar drift only in the midplane of the infalling envelope. Future observations with higher angular resolutions (~0″1) are needed to examine this possibility and ambipolar diffusion on a smaller scale.

1. Introduction

With recent interferometric observations at (sub-)millimeter wavelengths, Keplerian disks with radii of tens to hundreds of au have been detected around several embedded Class 0 and I protostars (Lommen et al. 2008; Takakuwa et al. 2012; Tobin et al. 2012; Brinch & Jørgensen 2013; Murillo et al. 2013; Ohashi et al. 2014; Chou et al. 2014, 2016; Harsono et al. 2014; Lindberg et al. 2014; Lee et al. 2014, 2016; Yen et al. 2014, 2017; Aso et al. 2015). On the other hand, there is a group of Class 0 protostars with envelope rotations on a 1000 au scale that are one order of magnitude slower than other Class 0 protostars (Brinch et al. 2009; Yen et al. 2010, 2015a; Maret et al. 2014), and they do not exhibit Keplerian disks with sizes larger than 10–20 au (Maury et al. 2010; Oya et al. 2014; Yen et al. 2017). The origin of the discrepancy in the gas kinematics and the disk sizes between these young protostars and others is not clear. It can be due to difference in their ages, initial rotation of their parental cores, and/or effects of the magnetic field (Yen et al. 2015a,b, 2017).

Molecular clouds are magnetized (Crutcher 2012). The magnetic field can slow down the gas motion in collapsing dense cores and transfer the angular momentum of the collapsing material outward, and consequently suppress the formation and growth of Keplerian disks around protostars (Allen et al. 2003). Ideal magnetohydrodynamic (MHD) simulations of collapsing dense cores where the rotational axis is aligned with the magnetic field show that no Keplerian disk with a size larger than 10 au can form as a result of efficient magnetic braking (e.g., Galli et al. 2006; Mellon & Li 2008; Joos et al. 2012). This is consistent with the observations of some Class 0 protostars exhibiting slow envelope rotation and Keplerian disks smaller than 10–20 au, but it contradicts other observations
showing an increasing number of Keplerian disks with radii larger than tens of au. In addition, 100 au scale Keplerian disks are often observed around T Tauri and Herbig Ae/Be stars (Williams & Cieza 2011). Simulations have demonstrated that when non-ideal MHD effects, dissipation of protostellar envelopes, initially misaligned rotational axis and magnetic field, more realistic treatment of ionization degrees, or turbulence are considered, the efficiency of magnetic braking can be reduced to enable the formation of Keplerian disks larger than 10 au (Hennebelle & Ciardi 2009; Krasnopolsky et al. 2011; Li et al. 2011, 2013; Machida & Matsumoto 2011; Machida et al. 2011, 2014; Dapp et al. 2012; Joos et al. 2012, 2013; Santos-Lima et al. 2012; Seifried et al. 2012, 2013; Padovani et al. 2013, 2014; Tomida et al. 2015a,b; Hennebelle et al. 2016; Zhao et al. 2016, 2018). Nevertheless, these mechanisms have not yet been observationally confirmed or constrained.

Ambipolar diffusion is one of the non-ideal MHD effects proposed to enable the formation of large-scale Keplerian disks. With ambipolar diffusion, ions and neutrals can have a relative drift, and the magnetic field, which is tied to the ions, is not dragged toward the center during the collapse as quickly as in the ideal MHD case (Li et al. 2014). Thus, the magnetic flux is redistributed and is partially left in an outer region, and the mass-to-flux ratio increases toward the center (e.g., Fig. 7 in Dapp et al. 2012 and Fig. 6 in Tomida et al. 2015). As a result, the efficiency of magnetic braking can be reduced to form 10 au or larger Keplerian disks depending on the magnetic diffusivity of ambipolar diffusion (e.g., Dapp et al. 2012; Tomida et al. 2015; Tsukamoto et al. 2015a; Masson et al. 2016; Zhao et al. 2016, 2018). Thus, observational studies comparing the motions of ionized and neutral gas are essential to understand ambipolar diffusion in protostellar sources and its effects on the formation and growth of Keplerian disks (e.g., Caselli et al. 2002a,b).

The isolated Bok globule B335 has an embedded Class 0 protostar (IRAS 19347+0727) at a distance of ∼100 pc (Keene et al. 1980, 1983; Stutz et al. 2008; Olofsson & Olofsson 2009). It is associated with a large-scale CO outflow (e.g., Hirano et al. 1988; Yen et al. 2010; Hull et al. 2014) as well as Herbig–Haro objects (Reipurth et al. 1992; Gälfalk & Olofsson 2007). The signatures of the infalling motion in B335 have been observed with single-dish telescopes and interferometers on scales from hundreds to thousands of au (Zhou et al. 1993; Zhou 1995; Choi et al. 1995; Evans et al. 2005, 2015; Saito et al. 1999; Yen et al. 2010; Kurono et al. 2013). B335 is slowly rotating with a decreasing specific angular momentum on scales from 0.1 pc to 1000 au (Saito et al. 1999; Yen et al. 2011; Kurono et al. 2013), and the radial profile of its specific angular momentum flattens at an inner radius of 1000 au (Yen et al. 2015b). No Keplerian disk with a size larger than 10 au is detected in B335 with the Atacama Large Millimeter/submillimeter Array (ALMA) observations (Yen et al. 2015b). Near-infrared polarimetric observations show that the magnetic field on a 0.2 pc scale in B335 is tilted from the outflow axis by 35°–60° (Bertrang et al. 2014). The structures of the magnetic field become more disordered and are misaligned with the outflow axis on a scale of a few thousand au, as revealed by single-dish and interferometric polarimetric observations at (sub-)millimeter wavelengths (Wolf et al. 2003; Davidson et al. 2011; Chapman et al. 2013; Hull et al. 2014). Because of its slowly rotating inner envelope and absence of a large disk, B335 is a promising candidate with efficient magnetic braking (Yen et al. 2015b). Therefore, B335 is an excellent target for probing the absence or existence of ambipolar diffusion and for studying the effects of the magnetic field in the process of star formation.

We here report our observational results of the H13CO+ (3–2; 260.255342 GHz) emission in B335 obtained with ALMA, and we compare the gas kinematics traced by the H13CO+ (3–2) line with the C18O (2–1) results presented in Yen et al. (2015b). C18O and H13CO+ are chemically similar (Lee et al. 2004; Aikawa et al. 2008), and both are expected to be abundant in the inner envelope on a scale of hundreds of au in B335 (Evans et al. 2005). The C18O (2–1) line has an upper energy level of 16 K and a critical density of ∼104 cm−3, and the H13CO+ (3–2) line has an upper energy level of 25 K and a critical density of ∼105 cm−3. The upper energy levels and critical densities of both lines are below the temperature and density in the protostellar envelope on a scale within a few hundred au in B335 (Harvey et al. 2003; Shirley et al. 2011), and both lines are expected to be optically thin on the scale based on the typical column densities of C18O and H13CO+ in protostellar envelopes on a scale of hundreds of au (Hogerheijde et al. 1998). Therefore we here adopt these two lines to trace the kinematics of the ionized and neutral gas in the protostellar envelope in B335, and we compare the measured infalling velocities from these two lines and discuss the implication of our results on the effects of ambipolar diffusion in B335.

2. Observations

The data of B335 presented in this paper were obtained with the ALMA observations with 40 antennas during the cycle-3 observing period on May 23 and June 3, 2016. The array configuration was C36-4 with the shortest baseline length of ∼15 m (∼13 k)}. Because of different array configurations, the shortest baseline length in the H13CO+ observations is half of that in the ALMA C18O observations with the C34-6 configuration (Yen et al. 2015b). With this shortest baseline length, our H13CO+ observations have a largest recoverable angular scale of ∼7′′ at a 50% level (Wilner & Welch 1994). The pointing center was α(J2000) = 19h37m00s89, δ(J2000) = +7°34′9″. The on-source integration time on B335 was ∼80 min. The correlator was configured in the frequency division mode, and a spectral window with a bandwidth of 117.2 MHz was assigned to the H13CO+ emission with 960 channels, resulting in a channel width of 122.1 kHz. The 1.2 mm continuum was observed simultaneously with a total bandwidth of 2 GHz. We have confirmed that the peak position of the 1.2 mm continuum emission is consistent with the 1.3 mm continuum emission in Yen et al. (2015b), so that there is no relative positional offset between the two data sets. The position of the continuum peak, which is the same as the pointing center, was adopted as the protostellar position. J1935 + 0531 (0.75 Jy at 260.2 GHz) and J2035 + 1056 (0.31 Jy at 260.2 GHz) were observed as gain calibrators in the first and second observations, respectively. J2148 + 0657 was observed as a bandpass and flux calibrator. Calibration of the raw visibility data was performed with the standard reduction script for the cycle-3 data, which uses tasks in Common Astronomy Software Applications (CASA; McMullin et al. 2007) of version 4.5.3. The image of the H13CO+ emission was generated with the Briggs robust parameter of 0 from the calibrated visibility data and CLEANed with the CASA task “clean” at a velocity resolution of 0.17 km s−1. This velocity resolution is the same as that in the C18O image obtained from Yen et al. (2015b). The achieved synthesized beam is 0′′.5 × 0′′.4 with a position angle (PA) of 111°, which is a factor of 1.5 larger than that of the C18O image. The achieved rms noise
13CO emission around the protostar is measured to be 1σ, and the PA of the elongation of the H 13CO+ emission, the PA of the elongation of the protostellar position. Red and blue arrows show the direction of the blue- and redshifted outflows, respectively. Contour levels in (a) are 3σ, 6σ, 10σ, 15σ, 20σ, 30σ, and 45σ, and in (b) are 3σ, 6σ, 10σ, 15σ, 25σ, and 40σ, where 1σ is 3.3 and 3.4 mJy beam$^{-1}$ km s$^{-1}$, respectively.

Fig. 2. Spectra of the C$^{18}$O and H$^{13}$CO$^+$ emission at the protostellar position obtained with our ALMA observations, shown in blue and green histograms. The data were first convolved with the same circular beam with a size of 0′′.5 to extract the spectra. A vertical dotted line denotes the systemic velocity of 8.34 km s$^{-1}$.

3. Results

Figure 1 presents the total integrated-intensity (moment 0) and mean intensity-weighted velocity (moment 1) maps of the H$^{13}$CO$^+$ and C$^{18}$O emission. The maps of the C$^{18}$O emission have been presented in Yen et al. (2015b) and are also shown here for a direct comparison with the H$^{13}$CO$^+$ maps. The distributions of both emission lines are centrally peaked at the protostellar position, and the H$^{13}$CO$^+$ emission exhibits a blueshifted extension on a scale of 5″ (500 au) toward the east. A similar blueshifted extension toward the east is also observed in the C$^{18}$O emission, but on a smaller scale. The observed H$^{13}$CO$^+$ emission is more extended than the C$^{18}$O emission because the shortest baseline length in the H$^{13}$CO$^+$ observations is almost half of that in the C$^{18}$O observations. The central parts of both emission lines are more elongated along the north–south direction. By fitting a two-dimensional Gaussian distribution to the central part of these emission lines, where the integrated intensity is >20σ in the H$^{13}$CO$^+$ emission and >10σ in the C$^{18}$O emission, the PA of the elongation of the H$^{13}$CO$^+$ and C$^{18}$O emission around the protostar is measured to be $-12^\circ \pm 19^\circ$ and $17^\circ \pm 11^\circ$, respectively. These elongations are perpendicular to the outflow direction with a PA of 99° (Hull et al. 2014) and are more aligned with the flattened envelope with a PA of 16° on a 100 au scale traced by the 1.3 mm continuum (Yen et al. 2015b). The H$^{13}$CO$^+$ and C$^{18}$O emission lines both exhibit a clear velocity gradient along the east–west direction, where the eastern side is more blueshifted and the western side is more redshifted. The direction of this velocity gradient is consistent with the associated outflow. As discussed in Yen et al. (2015b), the blueshifted extended emission toward the east is most likely related to the blueshifted outflow, and the velocity gradient in the central part, where the emission is elongated along the direction of the flattened envelope, can be due to the infalling motion in the envelope.

Figure 2 presents the spectra of the C$^{18}$O and H$^{13}$CO$^+$ emission at the protostellar position. To compare the spectra of the two lines obtained with different observations, both data were first convolved with the same circular beam with a size of 0′′.5, and the intensity is converted into brightness temperature in units of K. Both emission lines show intensity peaks at similar velocities, $V_{LSR}$ of 8 and 9 km s$^{-1}$ as well as a dip close to the systemic velocity of $V_{LSR} = 8.34$ km s$^{-1}$. The H$^{13}$CO$^+$ emission additionally shows a redshifted line wing at $V_{LSR} > 10.5$ km s$^{-1}$. We integrated the H$^{13}$CO$^+$ emission over the three different velocity regimes, low velocity ($V_{LSR} = 7.9–8.3$ and 8.3–9.1 km s$^{-1}$), high velocity ($V_{LSR} = 6–7.9$ and 9.1–10.8 km s$^{-1}$), and very high velocity ($V_{LSR} = 10.8–12$ km s$^{-1}$), shown in Fig. 3. Similar maps of the C$^{18}$O emission have been presented in Yen et al. (2015b). The extended emission is primarily observed at the low velocities, and the emission is elongated along the north–south direction with a blueshifted extension toward the east.
A separated redshifted component is seen at ~7″ southwest to the protostar, possibly associated with the wall of the outflow cavity. Thus, at the low velocities, the H$^{13}$CO$^+$ emission likely traces the flattened envelope with a possible contamination from the outflow. On the other hand, at high velocities, blue- and redshifted compact components with a size of ~2″ (200 au) are clearly seen and are not surrounded by any extended structures, suggesting that the emission becomes less contaminated by the outflow. There is an additional component at even higher velocities, which is not resolved with our observations. The linear velocity gradient along the major axis of the envelope in the C$^{18}$O emission is measured to be 40.5 km s$^{-1}$ arcsec$^{-1}$ from the high-velocity ([ΔV] > 1.2 km s$^{-1}$) channels in the C$^{18}$O PV diagram (Yen et al. 2015b). From this linear velocity gradient, the peak offset between blueshifted and redshifted emission at ΔV of ±1.2 km s$^{-1}$ is expected to be 0′′.06. At ΔV of ±1.2 km s$^{-1}$, the signal-to-noise ratios (S/N) of the H$^{13}$CO$^+$ emission in our observations is ~10 at the peaks. The relative positional accuracy of our observations at these velocities is approximately the angular resolution of 0′′.5 divided by the S/N of 10, yielding 0′′.05, which is comparable to the expected positional offset from the velocity gradient. Therefore, the angular resolution of our H$^{13}$CO$^+$ observations is not sufficient to resolve the velocity gradient observed in the C$^{18}$O emission. We are thus not able to detect the slow envelope rotation on a 100 au scale, which we did observe in the C$^{18}$O and SO emission, with our H$^{13}$CO$^+$ observations.

### 4. Kinematical models of infalling and rotational motions

The central component with a radius of 2″ in the H$^{13}$CO$^+$ emission is elongated along the major axis of the flattened envelope and is perpendicular to the outflow direction (Fig. 1). Its velocity features can be explained with infalling motion in an edge-on envelope (Fig. 4). Thus, the central H$^{13}$CO$^+$ emission likely traces the infalling flattened envelope around B335, and no envelope rotation is detected in the H$^{13}$CO$^+$ line. To measure the infalling velocity in the H$^{13}$CO$^+$ line, we constructed kinematical models of an infalling flattened envelope to fit the observed velocity structures in the PV diagrams of the H$^{13}$CO$^+$ emission. In order to compare the infalling velocities measured in the H$^{13}$CO$^+$ and C$^{18}$O lines, we also reanalyzed the C$^{18}$O data with the same kinematical models adopted in this work.

The model envelope has three dimensions and is assumed to have power-law density and temperature profiles. Its number
radial profiles of the infalling and rotational velocity (of the H\textsuperscript{13}CO\textsuperscript{+} slope is twice larger than the maximum recoverable angular scale adopted to be 7′′. The outer radius is characteristic radius adopted to be 100 au. The outer radius of the model envelope are described as profile. Thus, the density and temperature profiles of the model change in the line intensity due to the different temperature results in a different fitted density profile, which compensates for temperature profile, and adopting a different temperature profile caly thin, the fitted velocity profile is not sensitive to the adopted As discussed in Yen et al. (2017), because the emission is opti-mally thin, the fitted velocity profile is not sensitive to the adopted temperature profile, and adopting a different temperature profile results in a different fitted density profile, which compensates for the change in the line intensity due to the different temperature profile. Thus, the density and temperature profiles of the model envelope are described as

\[ n(r) = n(R_0) \times \left( \frac{r}{R_0} \right)^p, \]  

\[ T(r) = 38 \times \left( \frac{r}{100 \text{ au}} \right)^{-0.4} \text{K}, \]  

where \( j \) is the specific angular momentum and \( \theta \) is the angle between the radius and the polar axis. As described below, the H\textsuperscript{13}CO\textsuperscript{+} and C\textsuperscript{18}O data are fitted separately. The best-fit \( n(R_0), p, V_\text{in}(R_0), \) and \( j \) can be different for the H\textsuperscript{13}CO\textsuperscript{+} and C\textsuperscript{18}O emission. We adopt the latest estimates of the distance of 100 pc (Olofsson & Olofsson 2009) and an inclination angle of 87° (Stutz et al. 2008) for B335 to compute the model images.

We first performed the \( \chi^2 \) fitting on the C\textsuperscript{18}O PV diagrams along the major and minor axes. The model images in the C\textsuperscript{18}O emission were computed on the assumption of the local thermal equilibrium (LTE) condition because the C\textsuperscript{18}O (2–1) line is expected to be thermalized with the typical physical condition \( n_\text{H}_2 > 10^4 \text{ cm}^{-3} \) in protostellar envelopes on a scale of a few hundred au (e.g., Shirley et al. 2000). Then we simulated ALMA observations of the model images with the same array configuration and coverage of hour angle as our real observations. Therefore, the effects of different \( u \) and \( \theta \) sampling and angular resolutions between the H\textsuperscript{13}CO\textsuperscript{+} and C\textsuperscript{18}O observations are included in our analysis. We generated synthetic images from the simulated visibility data with the same imaging parameters as Yen et al. (2015b) and extracted PV diagrams from the synthetic images. The channels at the low velocities of \( V_{\text{LSR}} = 7.7–8.9 \text{ km s}^{-1} \) (vertical dashed lines in Fig. 5) are excluded in the fitting to have minimal contamination from the extended structures and the outflows. As demonstrated in Yen et al. (2015b), the envelope rotation is so slow that it does not affect the measurements of the infalling velocity. In addition, the signature of the envelope rotation is not detected in the H\textsuperscript{13}CO\textsuperscript{+} emission. Thus, the fitting was performed with two fixed \( j, 3 \times 10^{-5} \text{ km s}^{-1} \text{ pc}, \) as derived from Yen et al. (2015b), with the correction of the different adopted distances, and \( \theta, \) meaning no rotation. We confirmed that the best-fit \( V_{\text{in}}(R_0) \) is the same with these two \( j \) because the gas kinematics is dominated by the infalling motion.

The best-fit results of the C\textsuperscript{18}O data are shown in Fig. 5 and are listed in Table 1. The \( \chi^2 \) of our best-fit model is 2.6. The uncertainties of our best-fit parameters are estimated from the parameter ranges of the models having \( \chi^2 \) less than the minimum \( \chi^2 + 1 \) (Table 1). Figure 6 presents \( \chi^2 \) as a function of \( V_{\text{in}}(100 \text{ au}) \) from our fitting results. In Appendix A, we present PV diagrams extracted from the synthetic images of our kinematical models with different \( V_{\text{in}}(100 \text{ au}) \) to demonstrate the dependence of the velocity structures on the infalling velocity. These comparisons

---

Fig. 4. Position–velocity diagram of the H\textsuperscript{13}CO\textsuperscript{+} emission along the (a) major and (b) minor axes of the flattened envelope passing through the protostellar position. Velocity axes are in units of km s\(^{-1}\) in the LSR frame, and offset axes are in arcsecond with respect to the protostellar position. Vertical and horizontal green lines denote the systemic velocity of 8.34 km s\(^{-1}\) and the protostellar position, respectively. Contour levels are 3\( \sigma \), 6\( \sigma \), 10\( \sigma \), 15\( \sigma \), and 20\( \sigma \) and then in steps of 10\( \sigma \); where 1\( \sigma \) is 3.3 mJy beam\(^{-1}\).
**Fig. 5.** Observed (black) and best-fit model (red; with parameters in Table 1) position–velocity diagrams of the C\textsuperscript{18}O (upper panels) and H\textsuperscript{13}CO\textsuperscript{+} (lower panels) emission along the major (left panels) and minor (right panels) axes of the flattened envelope passing through the protostellar position. Vertical and horizontal dotted lines denote the systemic velocity of 8.34 km s\textsuperscript{-1} and the protostellar position, respectively. Vertical green dashed lines show the velocity range that was not included in our model fitting, \(V_{\text{LSR}}\) of 7.7–8.9 km s\textsuperscript{-1}, because of a possible contamination from the outflow. Contour levels are from 3\(\sigma\) in steps of 5\(\sigma\), where 1\(\sigma\) is 3.8 mJy beam\textsuperscript{-1} in the C\textsuperscript{18}O emission and is 3.3 mJy beam\textsuperscript{-1} in the H\textsuperscript{13}CO\textsuperscript{+} emission.

**Table 1.** Best-fit parameters of kinematical models.

|          | C\textsuperscript{18}O (2–1) | H\textsuperscript{13}CO\textsuperscript{+} (3–2) |
|----------|-------------------------------|-----------------------------------------------|
| \(V_{\text{in}}\) (100 au) | 0.85 ± 0.2 km s\textsuperscript{-1} | 0.85 ± 0.2 km s\textsuperscript{-1} |
| \(n\) (100 au) | 2.7 ± 1.2 cm\textsuperscript{-3} | \(4 ± 1\) \times 10\textsuperscript{-4} cm\textsuperscript{-3} |
| \(p\) | −2.1 ± 0.5 | −2.1 ± 0.5 |

show that the infalling velocity at a radius of 100 au is most likely within the range of 0.85 ± 0.2 km s\textsuperscript{-1}.

The best-fit C\textsuperscript{18}O number density is 2.7 cm\textsuperscript{-3}. On the assumption of a typical C\textsuperscript{18}O abundance of \(3 \times 10\textsuperscript{-7}\) relative to H\textsubscript{2} (Frerking et al. 1982), the H\textsubscript{2} number density is estimated to be \(9 \times 10\textsuperscript{6}\) cm\textsuperscript{-3}. In addition, the C\textsuperscript{18}O abundance in the protostellar envelope in B335 is possibly lower than the typical value in the interstellar medium (ISM) by a factor of ten (Evans et al. 2005; Yen et al. 2010), and this leads to an even higher H\textsubscript{2} number density.

**Fig. 6.** \(\chi^2\) as a function of infalling velocity at a radius of 100 au of our kinematical models for C\textsuperscript{18}O (blue curve) and H\textsuperscript{13}CO\textsuperscript{+} (green curve). For each infalling velocity, \(\chi^2\) presented here is the smallest \(\chi^2\) achieved by varying all the other parameters. The minimum \(\chi^2\) for the neutral and ionized lines are at 0.85 km s\textsuperscript{-1}.

same process as described above, and performed the \(\chi^2\) fitting on the H\textsuperscript{13}CO\textsuperscript{+} PV diagrams along the major and minor axes. The best-fit results of the H\textsuperscript{13}CO\textsuperscript{+} emission are also shown in Fig. 5.
and are listed in Table 1. The $\chi^2$ of our best-fit model for H$^{13}$CO$^+$ is 3, and $\chi^2$ as a function of $V_{\text{up}}(100 \text{ au})$ from our fitting results is shown in Fig. 6. For comparison with the best-fit model, PV diagrams extracted from the synthetic images of the kinematical models with different $V_{\text{in}}(100 \text{ au})$ for H$^{13}$CO$^+$ are presented in Appendix A.

In addition, to examine the influence of the uncertainty in the PA of the major and minor axes on our fitting results, we have changed the PA by $\pm 10^\circ$ and performed the same $\chi^2$ fitting. The resulting best-fit infalling velocities remain unchanged. Thus, our results are not sensitive to the uncertainty in the PA of the major and minor axes. Furthermore, we note that in the non-ideal MHD simulations (e.g., Li et al. 2011; Zhao et al. 2018), the radial profile of infalling velocity can be shallower than our assumed profile, $r^{-0.5}$, and the velocity profile of ions can be almost flat or even decrease with decreasing radii when the matter and the magnetic field are decoupled. Nevertheless, our data show that the line widths of the C$^{18}$O and H$^{13}$CO$^+$ emission increase with decreasing radii (Fig. 5), suggesting that the matter and the magnetic field are decoupled. Nevertheless, our data show that the line widths of the C$^{18}$O and H$^{13}$CO$^+$ emission increase with decreasing radii (Fig. 5), suggesting that the matter and the magnetic field are decoupled. Nevertheless, our data show that the line widths of the C$^{18}$O and H$^{13}$CO$^+$ emission increase with decreasing radii (Fig. 5), suggesting that the matter and the magnetic field are decoupled.

If H$^{13}$CO$^+$ is attached to the magnetic field on a 100 au scale in B335, the velocity difference between H$^{13}$CO$^+$ and C$^{18}$O can trace the ambipolar drift velocity, which is the relative velocity between the magnetic field and the neutrals. Whether H$^{13}$CO$^+$ is attached to the magnetic field depends on the ratio between the Lorenz force and the drag force on H$^{13}$CO$^+$, and it can be evaluated with the Hall parameter ($\beta_{\text{HI}}$; Zhao et al. 2016),

$$\beta_{\text{HI}} = \frac{ZeB}{m_e c} \cdot \frac{m_i + m_e}{\mu m_i n(H_2) (\langle v \rangle^2)_{\text{HI}}},$$

where $m_i$ and $Ze$ are the mass and the charge of H$^{13}$CO$^+$, $B$ is the magnetic field strength, $c$ is the speed of light, $\mu$ is the mean molecular weight of 2.36, $m_i$ and $m_e$ are the masses of atomic and molecular hydrogen, $n(H_2)$ is the number density of H$_2$, and $\langle v \rangle_{\text{HI}}$ is the momentum transfer rate coefficient. When $\beta_{\text{HI}} \gg 1$, meaning that the Lorenz force dominates over the drag force, H$^{13}$CO$^+$ is attached to the magnetic field. At a radius of 100 au in B335, n(H$_2$) is estimated to be 9 $\times$ 10$^6$ cm$^{-3}$ with the ISM C$^{18}$O abundance in Sect. 4. $\langle v \rangle_{\text{HI}}$ is a function of temperature and velocity difference between ions and neutrals ($v_0$), and $\langle v \rangle_{\text{HI}} \ll v_0^{0.6}$ for HCO$^+$ (Pinto & Galli 2008). Our results suggest that $v_0$ is less than 0.3 km s$^{-1}$. With the formulae in Pinto & Galli (2008), $\langle v \rangle_{\text{HI}}$ is estimated to be 1.2 $\times$ 10$^6$ cm$^{-1}$ at a temperature of 38 K and $v_0$ of 0.3 km s$^{-1}$. With the method described by Chandrasekhar & Fermi (1953), B has been estimated to be 10–40 $\mu$G on a 0.1 pc scale from the infrared polarimetric observations (Bertrang et al. 2014) and to be 134 $\pm$ 39 $\mu$G on a 4000 au scale from the polarized thermal dust emission at the submillimeter wavelengths (Wolf et al. 2003) in B335. On the other hand, if the simple power-law relation between the magnetic field strength and the density in molecular clouds, $B = 0.143 \times n(H_2)^{0.5} \mu$G, is valid in B335 (Nakano et al. 2002), B is estimated to be 400 $\mu$G on a 100 au scale with our estimated n(H$_2$). In other protostellar sources, B on a scale of a few hundred au has been estimated to be even higher with $\approx$ 5 mG from the polarized thermal dust emission (Girart et al. 2006; Hull et al. 2017). It thus seems very plausible to have B of a few hundred $\mu$G in B335 on a 100 au scale. Still, with a conservative value of B > 100 $\mu$G, $\beta_{\text{HI}}$ is estimated to be $> 20$ on a 100 au scale. Therefore, on the assumptions of the typical magnetic field strength and C$^{18}$O abundance in protostellar sources, H$^{13}$CO$^+$ is expected to be attached to the magnetic field on a 100 au scale in B335.

In non-ideal MHD theoretical calculations and simulations incorporating ambipolar diffusion, the ambipolar drift velocity starts to increase on a scale of tens to hundreds of au in infalling protostellar envelopes, where the magnetic field starts to decouple from the neutral gas (e.g., Fig. 7 in Krasnopol’ský & Königl 2002, Fig. 3 in Mellon & Li 2009, Fig. 5 in Li et al. 2011, and Fig. 1 in Zhao et al. 2018). The radius, where the magnetic field starts to decouple from the neutral gas, is proportional to the magnetic diffusivity of ambipolar diffusion (Krasnopolsky & Königl 2002; Zhao et al. 2016, 2018). In the simulations with a standard Mathis–Rumpl–Nordsieck (MRN) grain size distribution (Mathis et al. 1977) and a typical cosmic-ray ionization rate of 10$^{-17}$ s$^{-1}$, the magnetic field is well coupled with the neutral gas and is dragged to the inner few hundred au or even a smaller scale in infalling envelopes (Li et al. 2011; Zhao et al. 2018). Then the magnetic field gradually decouples from the neutral gas in the inner regions and diffuses outward to form an ambipolar diffusion shock, which efficiently decelerates the infalling and rotational motions. (e.g., Krasnopolsky & Königl 2002; Li et al. 2011). In this case, the formation of a Keplerian disk with a size...
larger than 10 au is suppressed because a large amount of magnetic flux is accumulated in the inner envelope and efficiently transports away the angular momentum of the infalling material (Mellon & Li 2009; Li et al. 2011). Several simulations have shown that incorporating ambipolar diffusion with a typical diffusivity does not enable large-scale Keplerian disks to form (e.g., Mellon & Li 2009; Li et al. 2011; Zhao et al. 2016, 2018). In these simulations, the ambipolar drift velocity is lower than 0.2 km s\(^{-1}\) at a radius of 100 au, increases to 0.3 km s\(^{-1}\) at a radius of 70 au, and is higherer than 1 km s\(^{-1}\) at radii smaller than 30 au, while the infalling velocities of the neutrals are 0.3, 0.5, and 1.5 km s\(^{-1}\) at radii of 100, 70, and 30 au, respectively, when the central protostellar mass is 0.57 \(M_\odot\) (Fig. 5 in Li et al. 2011). If the ions are attached to the magnetic field, such an ambipolar drift velocity implies that the ion velocity is lower than 30\%–40\% of the neutral velocity.

On the other hand, the ambipolar diffusivity is enhanced by one to two orders of magnitude when small dust grains with sizes of a few to tens of nanometers are removed from the grain size distribution (Dapp et al. 2012; Padovani et al. 2014; Zhao et al. 2016). As a consequence, the magnetic field starts to decouple from the neutrals on a larger scale of several hundred or even few thousand au. In the simulations, the ambipolar drift velocity can be larger than 0.5 km s\(^{-1}\) at radii of 100–300 au and increase to 1 km s\(^{-1}\) at a radius of 100 au when the protostellar mass is 0.07 \(M_\odot\) (Zhao et al. 2018). This effect enables the formation of Keplerian disks with sizes of tens of au in the simulations (Masson et al. 2016; Zhao et al. 2016, 2018). We note that in such a paradigm with an enhanced ambipolar diffusivity, the formation of large-scale Keplerian disks with a typical mass-to-flux ratio of a few can still be suppressed when the initial rotation\(^1\) of parental cores is slow with an angular velocity lower than (5–8) \times 10^{-14} \text{s}^{-1}, corresponding to a ratio of rotational to gravitational energy of 0.5–1.6\% (Dapp et al. 2012; Tomida et al. 2015; Zhao et al. 2018).

With our observations, we set an upper limit to the velocity difference between the ionized and neutral gas at a radius of 100 au to be 0.3 km s\(^{-1}\) in B335. Our results are consistent with the non-ideal MHD simulations with the ambipolar diffusivity computed with the standard MRN grain size distribution, where the ambipolar drift velocity is expected to be <0.2 km s\(^{-1}\) at a radius of 100 au. Since our observations are not able to resolve the inner region of a few tens of au, we are not able to further unambiguously detect any increase in drift velocity toward the inner regions, which is predicted in the simulations. On the contrary, our observational results of B335 are inconsistent with the non-ideal MHD simulations with the enhanced ambipolar diffusivity and the removal of the small dust grains\(^2\), where the minimum grain size is 0.1 \(\mu\)m. The ambipolar drift velocity of 0.5–1 km s\(^{-1}\) on a scale of 100 au predicted in these simulations with the enhanced ambipolar diffusivity is not detected in B335 with our observations.

Therefore, based on the fact that H\(^13\)CO\(^+\) is likely well coupled to the magnetic field and that there is no measurable difference in the infall velocities between H\(^13\)CO\(^+\) and C\(^18\)O on a 100 au scale probed by our observations, our results suggest that in B335 any significant magnetic decoupling from the bulk neutral matter, if present, likely occurs on a scale smaller than 100 au, as in the non-ideal MHD simulations with the typical ambipolar diffusivity. Therefore, the magnetic field is dragged and accumulated on the small scale, and magnetic braking can efficiently remove the angular momentum from the material infalling to the small scale and suppress the disk formation in B335. This can result in the absence of a Keplerian disk with a size larger than 10 au in B335, as found in the observations (Yen et al. 2015b).

There are also other non-ideal MHD simulations that only incorporate Ohmic dissipation but no ambipolar diffusion (e.g., Dapp & Basu 2010; Tomida et al. 2013). These simulations, which resolve the formation of first cores, show that small Keplerian disks with a size of few au can form during the phase of first cores or during the formation of second cores. These simulations were unable to follow the evolution of the Keplerian disks further. Although it is not clear whether the size of these small disks will grow to a scale of 100 au as expected (Tomida et al. 2015) or remains on a scale of 10 au (Dapp et al. 2012), in these simulations the magnetic field is decoupled from the neutral gas in the innermost regions. B335 can also be an observational analog to these simulations. In addition, the non-detection of the velocity difference between the ionized and neutral gas is also consistent with the ideal MHD case. Nevertheless, no Keplerian disk is expected to form in the ideal MHD case unless the magnetic field is weak and largely misaligned from the rotational axis of parental cores (Mellon & Li 2008; Joos et al. 2012; Li et al. 2013), while the presence of the outflow and jets in B335 suggests that there is at least a small rotating disk around the protostar (e.g., Blandford & Payne 1982; Pudritz & Norman 1983, 1986). Thus, B335 is less likely the ideal MHD case. Future observations with higher angular resolutions to measure the velocity difference between the ionized and neutral gas on a scale of tens of au in B335 are needed to distinguish these simulations and the ones with the typical ambipolar diffusivity.

We also note that the velocity drift between ionized and neutral gas is expected to be most significant in the midplane of infalling protostellar envelopes, where the magnetic field is highly pinched, and there is almost no velocity drift in the upper layers of envelopes, as discussed in Krasnopolsky & Königl (2002) and Zhao et al. (2018). Although the inclination of B335 is edge on, the most suitable case to probe the gas motions in the midplane, our observations may not be able to distinguish the gas motions in the midplane and upper layers in the protostellar envelope in B335 because of the limited angular resolution, and the signature of the velocity drift (if present) is possibly diluted and smoothed out. Further observations with an angular resolution of ~0′′1 to resolve the vertical velocity structures within 10–20 au from the midplane at radii of 100–200 au are required to examine this possibility.

Finally, if the magnetic field strength on a 100 au scale in B335 is only a few tens of \(\mu\)G rather than >100 \(\mu\)G, specific ion species such as H\(^13\)CO\(^+\) are not the ideal indicator of the kinematics of the magnetic field because they are detached from the magnetic field (\(\beta_{\text{H}_2}=1\)). In this case, ions and neutrals in the inner 100 au region can move together, but the magnetic field can still be left behind the bulk infall motion. This picture of ions detached from the magnetic field is also consistent with our non-detection or upper limit of the velocity difference between ions and neutrals at a radius of 100 au. In this case, the magnetic field is not dynamically important in the infalling protostellar envelope (Mellon & Li 2009). The Keplerian disk is expected to grow in size with the proceeding collapse (Tereby et al. 1984; Basu 1998), and the absence of a Keplerian

---

1. The initial core rotation is assumed to be rigid-body rotation in the simulations.
2. In non-ideal MHD simulations incorporating ambipolar diffusion, the ambipolar drift velocity is expected to lower when the minimum size in the grain size distribution is smaller (Zhao et al. 2018).
6. Summary

We analyzed the data of the H$^{13}$CO$^+$ (3–2) and C$^{18}$O (2–1) emission in the Class 0 protostar B335 obtained with our ALMA observations. The goal is to investigate ambipolar diffusion in protostellar envelopes by comparing the gas motions traced by the ionized and neutral molecular lines. Our main results are summarized below.

- The H$^{13}$CO$^+$ and C$^{18}$O emission lines both show a central compact component with a size of 1″−2″ (100–200 au) elongated perpendicular to the outflow direction, and there are additional blueshifted extensions toward the east. Clear velocity gradients along the outflow direction are observed in both lines. The extensions toward the east are likely associated with the outflow. The elongated central components in the H$^{13}$CO$^+$ and C$^{18}$O emission likely trace the flattened envelope around the protostar, and their velocity structures can be explained with an edge-on infalling envelope.

- We constructed kinematical models of an infalling and rotating envelope and fitted the observed velocity structures in the PV diagrams along the major and minor axes of the flattened envelope in the H$^{13}$CO$^+$ and C$^{18}$O emission. The infalling velocities traced by the H$^{13}$CO$^+$ and C$^{18}$O emission are both measured to be 0.85±0.2 km s$^{-1}$ at a radius of 100 au, suggesting that the velocity difference between the ionized and neutral gas is at most 0.3 km s$^{-1}$ at a radius of 100 au.

- The Hall parameter of H$^{13}$CO$^+$ is estimated to be $\gg$1 on a 100 au scale in B335 on the assumption of a typical magnetic field strength of $>$100 $\mu$G on a 100 au scale in protostellar envelopes. Thus, H$^{13}$CO$^+$ is expected to be attached to the magnetic field, and the difference in the infalling velocities measured in the H$^{13}$CO$^+$ and C$^{18}$O lines can trace the ambipolar drift velocity.

- Our non-detection or upper limit of the ambipolar drift velocity suggests that the magnetic field and the bulk neutral matter remain well coupled on a 100 au scale, and any significant decoupling, if present, likely occurs on smaller scales than probed by our observations. Consequently, the magnetic field is dragged and accumulated on the small scale, and efficient magnetic braking can suppress the disk formation if the magnetic field is not dynamically important in the infalling protostellar envelope.

and there would be no difference in the infalling velocities traced by the H$^{13}$CO$^+$ and C$^{18}$O emission. In this case, the magnetic field is not dynamically important in the infalling protostellar envelope.

Appendix A: Position–velocity diagrams of kinematical models

Figure A.1 compares the observed PV diagrams with models with different \( V_{\text{in}} \) (100 au) from 0.4 km s\(^{-1}\) to 1.2 km s\(^{-1}\). For these models, all the other parameters, \( n(R_0) \) and \( p \), were varied to minimize \( \chi^2 \) with the given \( V_{\text{in}} \) (100 au). This comparison shows that when \( V_{\text{in}} \) (100 au) is beyond the range of 0.85 ± 0.2 km s\(^{-1}\), the line widths in the models become wider or narrower than the observations for both C\(^{18}\)O and H\(^{13}\)CO\(^{+}\), especially at offsets from 0.5′′ to 1′′, and the velocities of the intensity peaks in the model PV diagrams are offset from the observations. These results suggest that the infalling velocities of the C\(^{18}\)O and H\(^{13}\)CO\(^{+}\) gas at a radius of 100 au are most likely within the range of 0.85 ± 0.2 km s\(^{-1}\).
