ABSTRACT
Models defined by moment conditions are at the center of structural econometric estimation, but economic theory is mostly agnostic about moment selection. While a large pool of valid moments can potentially improve estimation efficiency, in the meantime a few invalid ones may undermine consistency. This article investigates the empirical likelihood estimation of these moment-defined models in high-dimensional settings. We propose a penalized empirical likelihood (PEL) estimation and establish its oracle property with consistent detection of invalid moments. The PEL estimator is asymptotically normally distributed, and a projected PEL procedure further eliminates its asymptotic bias and provides more accurate normal approximation to the finite sample behavior. Simulation exercises demonstrate excellent numerical performance of these methods in estimation and inference.

1. Introduction
Economists’ perennial pursuit of structural mechanisms leads to models defined by moments. These models can be written in a semiparametric form $\mathbb{E}[g(X; \theta_0)] = 0$, where $g = (g_1, \ldots, g_r)$ is a vector of $r$ estimating functions, $\theta_0$ is a vector of unknown parameters, and $X$ is observed data. To estimate these models, the most popular method is generalized method of moments (GMM) (Hansen 1982). Empirical likelihood (EL) (Qin and Lawless 1994) is a competitive alternative to GMM, thanks to its nice statistical properties. Both GMM and EL are essential building blocks of modern econometrics (Anatolyev and Gospodinov 2011).

Ideally, economists count on economic theory to guide the choice of variables and moments. However, the truth is that most economic theories are parsimonious abstractions and rarely pinpoint these choices in data-rich environments. The indeterminacy of moment selection brings about three related issues. The first is weak moments (Stock, Wright, and Yogo 2014), which threatens identification of the true value $\theta_0$ when multiple $\theta$’s satisfy $\mathbb{E}[g(X; \theta)] \approx 0$. Practitioners respond to the concerns of weak moments by adding more moment conditions in the hope to strengthen identification, causing the second issue of many moments (Roodman 2009). The hazard of many moments is the possible inclusion of invalid moments, meaning $\mathbb{E}[g_j(X; \theta_0)] \neq 0$ for some $j \in \{1, \ldots, r\}$ (Murray 2006), which is the third issue. These cited survey articles highlight the unease incurred by the three challenges and econometricians’ efforts in coping with them.

When an underlying economic theory is ambivalent, empirical results based on it can be controversial and susceptible to cherry-picking. In such a circumstance, of great importance are data-driven methods to guide and discipline moment selection. In the low-dimensional settings, Andrews and Lu (2001) propose the GMM information criteria, and Hong, Preston, and Shum (2003) follow with the counterpart for EL. Information criteria are evaluated exhaustively at all combinations of moments, and the computation becomes infeasible when there are many potential moments. To overcome this challenge, Liao (2013) ushers the adaptive Lasso shrinkage into GMM to select among a finite number of moments, and Cheng and Liao (2015) further extend it to deal with a diverging number of moments and accommodate invalid ones.

Unprecedented progress in computation and information technology fuel an arms race between the sheer size of the data and the scale of empirical models. In the era of big data, on the one hand the cost of data collection and processing is tremendously lowered and rich datasets open new perspectives to inspect a myriad of problems; on the other hand economists attempt to build general models to capture various sources of heterogeneity in observational data. Empirical applications abound with models of many potential moments. For instance, Eaton, Kortum, and Kramarz (2011) create 1360 moments to estimate a structural trade model, Altonji, Smith, and Vidangos (2013) match 2429 moments implied by a model of earning dynamics, and early works of linear instrumental variables (IV) models produce thousands of instruments by interacting variables (Angrist and Krueger 1992). Although the sample sizes in these examples are nontrivial, the proliferation of moments calls for a moment selection procedure capable of handling high-dimensional moments at a magnitude unrestricted by the...
sample size. In particular, invalid ones that jeopardize consistency must be identified and “culled” from the herd of moments.

The quadratic form of the usual GMM criterion function is incompatible with high-dimensional moments (Shi 2016a, 2016b), and thus Belloni et al. (2018) regularize GMM with the sup-norm. In this article, we contribute the most general and versatile procedure for high-dimensional nonlinear settings, to the best of our knowledge. We first develop a penalized empirical likelihood (PEL) solution (Chang, Tang, and Wu 2018) to deal with valid and invalid moments simultaneously. We neutralize the invalid moments by an auxiliary parameter, following Liao (2013) and Cheng and Liao (2015). We establish the rate of convergence and asymptotic normal distribution of the PEL estimator, and show the efficiency gain from incorporating extra valid moments. Under suitable conditions, it transpires that PEL enjoys the oracle property of consistent moment selection and parameter selection.

The asymptotic normal distribution of the PEL estimator involves a bias term caused by the high-dimensional moments. To spare the estimation of the bias term, we can take further actions to project out the influence of the high-dimensional nuisance parameter in the PEL estimator, which is called projected PEL (PPEL) (Chang et al. 2021). The asymptotic normality of the PPEL estimator is free of bias, which facilitates statistical inference of the structural parameter as well as the validity of moments. Invoking statistical learning to assist our decisions, our method fits well in the recent trend of machine learning for the automatic selection of moments and variables.

Although this article follows Chang, Tang, and Wu (2018) for estimation and Chang et al. (2021) for inference procedures, the key insight lies in the observations that the high-dimensional auxiliary parameter, which signifies the magnitude of misspecification, can be incorporated in the EL method as an additional high-dimensional parameter. In this article, “high-dimensional” means that the numbers of parameters and/or moments are larger than the sample size, which goes beyond the scope of Liao (2013) and Cheng and Liao (2015). On the other hand, in order to adapt Chang, Tang, and Wu (2018) and Chang et al. (2021) to accommodate misspecified moments, we must deal with the distinctive roles of the main parameter of interest and the auxiliary parameter in identification and the technical challenges induced by them. Differences from Chang, Tang, and Wu (2018) are highlighted in Section 3 about the rates of convergences of the two components of the parameters, and those from Chang et al. (2021) are elaborated in Section 5 about the ways of confidence region construction.

**Literature review.** Our article stands on strands of literature, which are too vast to survey exhaustively. The accumulation of moments started from the linear IV model (Angrist 1990; Angrist and Keueger 1991). The linear IV model motivates theoretical research on issues of many IV (Bekker 1994), weak IV (Stock and Yogo 2005; Andrews and Cheng 2012), many weak IV (Chao et al. 2011; Hansen and Kozburz 2014), invalid moments and many invalid IV (Kolesář et al. 2015; Windmeijer et al. 2019), to name a few. In high-dimensional contexts, Belloni et al. (2012) use Lasso method for IV selection in the first stage, and Belloni, Chernozhukov, and Hansen (2014) deal with post-selection inference. Using the linear structure, Gold, Lederer, and Tao (2020) and Caner and Kock (2018) provide inferential procedures for low-dimensional parameters in models with high-dimensional endogenous parameters and high-dimensional IVs. Our method includes the linear IV model as a special case. In particular, the case of high-dimensional structural parameters is elaborated in Section 4.

The proliferation of moments spreads from linear IV models to nonlinear models. For example, in empirical industrial organization researchers bring in moments from various resources, some of which are guided by economic theory, to mitigate the concerns of weak identification and improve estimation efficiency (Ackerberg et al. 2007). In empirical macroeconomics, identification failure and moment misspecification are common issues (Mavroeidis 2005). Under the GMM framework, inference under weak moments (Stock and Wright 2000; Kleibergen 2005; Andrews and Mikusheva 2020), estimation under many weak moments (Han and Phillips 2006), and robust procedures for invalid moments (DiTraglia 2016; Caner, Han, and Lee 2018) have been developed.

EL’s attractive theoretical properties are studied extensively (Kitamura 2001; Otsu 2010; Matsushita and Otsu 2013; Chang, Chen, and Chen 2015). Otsu (2006) and Newey and Windmeijer (2009) deal with its inference under weak IV, and Caner and Fan (2015) select instruments in linear IV models. Penalization schemes on EL have been introduced by Otsu (2007), Tang and Leng (2010) and Chang, Tang, and Wu (2018).

**Organization.** The rest of the article is organized as follows. Section 2 introduces the model and the analytic framework. We first derive the asymptotic properties of our estimation in the low-dimensional case in Section 3, extend them to the high-dimensional structural parameter in Section 4, and we further refine PEL with projection to eliminate its bias in Section 5. The theoretical results are supported in Section 6 by Monte Carlo simulations. The influential study of the determinants of economic outcomes after colonialism is revisited in Section 7. Section 8 concludes the article. Due to the limitations of space, the proofs and the technical details of secondary importance are relegated into the supplementary materials.

**Notations.** We conclude this Introduction with notations used throughout the article. “Low-dimensional” refers to the case that the numbers of parameters or moments is much smaller than the sample size, whereas “high-dimensional” refers to the opposite. For two sequences of positive numbers \(a_n\) and \(b_n\), we write \(a_n \lesssim b_n\) or \(b_n \gtrsim a_n\) if there exists a positive constant \(c\) such that \(\limsup_{n\to\infty} a_n/b_n \leq c\), and write \(a_n \ll b_n\) or \(b_n \gg a_n\) if \(\limsup_{n\to\infty} a_n/b_n = 0\).

Denote by \(1(\cdot)\) the indicator function. For a positive integer \(q\), we write \([q] = \{1, \ldots, q\}\). For a \(q \times q\) symmetric matrix \(M\), denote by \(\lambda_{\min}(M)\) and \(\lambda_{\max}(M)\) the smallest and largest eigenvalues of \(M\), respectively. For a \(q_1 \times q_2\) matrix \(B = (b_{ij})_{q_1 \times q_2}\), let \(B^\top\) be its transpose, \(B^{o2} = BB^\top\), \(B^{\kappa} = (|b_{ij}|^\kappa)^{1/2}\) for any \(\kappa > 0\), \(|B|_\infty = \max_{\{1,2\}}\max_{i\in[q_1],j\in[q_2]} |b_{ij}|\) be the sup-norm, and \(|B|_2 = \lambda_{\max}(B^{o2})\) be the spectral norm. Specifically, if \(q_1 = q_2 = 1\), we use \(|B|_\infty = \max_{i\in[q_1]} |b_{i1}|\), \(|B|_1 = \sum_{i=1}^{\min(q_1,q_2)} |b_{i1}|\) and \(|B|_2 = (\sum_{i=1}^{\min(q_1,q_2)} b_{i1}^2)^{1/2}\) to denote the \(L_\infty\) norm, \(L_1\) norm and \(L_2\)-norm of the \(q_1\)-dimensional vector \(B\), respectively. For two square matrices \(M_1\) and \(M_2\), we say \(M_1 \preceq M_2\) if \((M_2 - M_1)\) is a positive semidefinite matrix.
The population mean is denoted by $\mathbb{E}(\cdot)$, and the sample mean by $\bar{X}_n(\cdot) = n^{-1} \sum_{i=1}^n \cdot$. For a given index set $\mathcal{L}$, let $|\mathcal{L}|$ be its cardinality. For a generic multivariate function $h(\cdot)$, we denote by $h(\cdot)$ the subvector of $h(\cdot)$ collecting the components indexed by $\mathcal{L}$. Analogously, we write $a_n$ as the corresponding subvector of $a$.

2. Empirical Likelihood with a Herd of Moments

In this section we introduce the model and the EL estimation.

2.1. EL Estimation with Valid Moments

Motivated from empirical applications in asset pricing, the two-step GMM (Hansen 1982) was the default estimation method for the moment-defined model (2.1). Intensive theoretical studies and numerical evidence in 1980s and 1990s revealed some key ideas about moments; some invalid ones may creep in. In these applications, researchers often have some ideas about the relative importance of moments; in the meantime, when researchers work with more and more moments, some invalid ones may creep in.

Example 1. Eaton, Kortum, and Kramarz (2011) deem as the key moments $128(=2^7)$ combinations of the largest seven trade partners of France, which are more important than the other 1232 moments. Angrist (1990) treats the date of birth (DOB) as the key IV and it is complemented by the IVs generated by interactions; recently Kolesár et al. (2015) raise the potential invalidity among these interaction terms.

To put into an analytic framework a herd of extra moments with unknown validity ex ante, suppose that $r_1$ estimating functions $g^{(D)}_j = (g^{(D)}_{j1}, \ldots, g^{(D)}_{jT})$ are partitioned into two groups:

$$
A = \{ j \in D : E[g^{(D)}_{j\lambda}(\theta_0)] = 0 \} \text{ and } A^c = \{ j \in D : E[g^{(D)}_{j\lambda}(\theta_0)] \neq 0 \}.
$$

Here the estimating functions in the set $A$ are correctly specified, which can help improve the efficiency in estimating $\theta_0$. On the contrary, those in $A^c$ are misspecified, and they can only undermine the identification of $\theta_0$.

If there is an "oracle" that reveals which components of $g^{(D)}_j$ belong to $A$, that is, the valid estimating functions, we can collect all valid estimating functions indexed by $\mathcal{H} := \mathcal{I} \cup A$ to estimate $\theta_0$. Denote $g^{(H)} = (g^{(H)}_1, \ldots, g^{(H)}_T)$ and $h = |\mathcal{H}|$ as the total number of valid moments. The associated EL estimation for $\theta_0$ based on the estimating functions $g^{(H)}$ is given by

$$
\hat{\theta}_{EL}(\mathcal{H}) = \arg\min_{\theta \in \Theta} \max_{\lambda \in \Lambda_0^{(\mathcal{H})}(\theta)} \sum_{i=1}^h \log(1 + \lambda_i^\top g^{(H)}_i(\theta)) ,
$$

where $\Lambda_0^{(\mathcal{H})}(\theta) = \{ \lambda \in \mathbb{R}^h : \lambda^\top g^{(H)}(\theta) \in \mathcal{V} \}$ for any $i \in [n]$. By the same arguments as those in Proposition A.1 in the supplementary materials, the following Proposition 2.1 verifies the asymptotic normality of $\hat{\theta}_{EL}(\mathcal{H})$.

**Proposition 2.1 (Oracle property).** Assume that $g^{(H)}$ satisfies the conditions (A.1)–(A.5) in the supplementary materials associated with $g^{(H)}$. If $h^2 n^{1/2-2/\gamma} = o(1)$ and $h^2 p^2 n^{-1} = O(1)$, we adopt the asymptotic framework of Hjort, McKeague, and Van Keilegom (2009) and Chang, Chen, and Chen (2015) to take the observations $(g^{(H)}_i(\theta))_{i=1}^n$ as a multi-index array, where $r_1, p$ and $d$ may depend on $n$. Proposition A.1 in the supplementary materials shows that the standard asymptotic normality for $\hat{\theta}_{EL}(\mathcal{H})$ holds under mild regularity conditions.

![Image](https://via.placeholder.com/150)

**2.2. Oracle EL Estimation**

In applied econometrics, there has been a tendency of assembling many IVs or creating many moments to identify the parameter of interest. In these applications, researchers often have some ideas about the relative importance of moments; in the meantime, when researchers work with more and more moments, some invalid ones may creep in.
In GMM estimation under a fixed $r$, Liao (2013) shrinks $\xi$ toward zero using the adaptive Lasso (Zou 2006).
in $\mathcal{P}$. When $P_\epsilon(\cdot) \in \mathcal{P}$, we write the associated $\rho(0^+; \tau)$ as $\rho(0^+)$ for simplification.

To establish the limiting distribution of $\hat{\theta}_{\text{PEL}}$ in (3.1), we assume the following regularity conditions.

**Condition 1.** There exists a universal constant $K_1 > 0$ such that
\[
\inf_{\theta \in \Theta} \mathbb{E}[\xi_i^2(T)(\theta)] \geq K_1 \varepsilon
\]
for all $\varepsilon > 0$.

**Condition 2.** There exist universal constants $K_2 > 0$ and $\gamma > 4$ such that
\[
\max_{j \in \mathcal{J}} \mathbb{E} \left[ \sup_{\theta \in \Theta} |\xi_i^2(T)(\theta)| | \gamma \right] \leq K_2.
\]

**Condition 3.** For each $j \in \mathcal{T}$, the function $g_j^0(T)(X; \psi)$ is twice continuously differentiable with respect to $\psi \in \Psi$ for any $X$. For $\gamma$ specified in Condition 2,
\[
\sup_{\psi \in \Psi} \left( \mathbb{E}_{\psi}[\{\xi_i^2(T)(\psi)\}^2] + \mathbb{E}_{\psi}[\{\xi_i^2(T)(\psi)\}^2] \right) = O_p(1).
\]

There is some universal constant $K_3 > 0$ such that $\sup_{\theta \in \Theta} \mathbb{E}[\xi_i^2(T)(\theta)] \leq K_3$.

For any index set $\mathcal{F} \subset \mathcal{T}$ and $\psi \in \Psi$, define $V(\psi) = \mathbb{E}_{\psi}[\{\xi_i^2(T)(\psi)\}^2]$. When $\mathcal{F} = \mathcal{T}$, we write $V^T(\psi) = V(T)(\psi)$ for conciseness.

**Condition 4.** There exists a universal constant $K_4 > 1$ such that $K_4^{-1} < \lambda_{\min}(V(T)(\psi_0)) \leq \lambda_{\max}(V(T)(\psi_0)) < K_4$.

**Conditions 1–4** are standard regularity assumptions in the literature. Condition 1 is an identification assumption of the estimating equations in the known set $\mathcal{I}$. Write $\xi_0 = (\xi_{0,k})_{k \in \mathcal{D}}$, and we continue by defining
\[
a_n = \sum_{k \in \mathcal{D}} P_{1,\pi}(\xi_{0,k}) \quad \text{and} \quad \phi_n = \max\{p_{0,1/2}, p_{1/2} n, v\}
\]
in this section, where $n = (n^{-1} \log r)^{1/2}$. Suppose:

- There exist $c_n \to 0$ and $\varepsilon_n \to 0$ with $\phi_n^{-1} \to 0$ such that\n-\nmax_{k \in \mathcal{A}} \sup_{0 < 1 \leq |\xi_{0,k}| + c_n} P_{1,\pi}(t) = O(\varepsilon_n)

(3.3)

to control the bias induced by $P_{1,\pi}(\cdot)$ on $\hat{\psi}_{\text{PEL}}$. With the assumption $\phi_n = o(\min_{k \in \mathcal{A}} |\xi_{0,k}|)$ that the nonzero components of $\xi_0$ do not diminish to zero too fast, (3.4) can be replaced by
\[
\max_{k \in \mathcal{A}} \sup_{0 < 1 \leq |\xi_{0,k}| + c_n} P_{1,\pi}(t) = O(\varepsilon_n)
\]
for some constant $c \in (0, 1)$. If we select $P_{1,\pi}(\cdot)$ as an asymptotically unbiased penalty such as SCAD or MCP, we have $\varepsilon_n = n$ in (3.5) when
\[
\min_{k \in \mathcal{A}} |\xi_{0,k}| \gg \max\{\phi_n, \pi\}.
\]
To simplify the presentation, in this section we assume that (3.6) holds and $\chi_n = 0$ in (3.5).3

3If (3.6) is violated, the asymptotic normality of $\hat{\psi}_{\text{PEL}}$ in Theorem 3.1 will still hold under (3.4) along with more complicated notations to spell out the restrictions.

To allocate the parameter of interest $\theta$ and those invalid moments in $\mathcal{A}$, we define an index set $S = \mathcal{P} \cup S'$ and its cardinality $s = |S|$. For any $\psi \in \Psi$, the set picks out $\psi_S = (\psi^T, \xi_i^S)^T$. Since $\mathcal{A} = S'$, $\mathcal{A} = (\mathcal{P} \cup \mathcal{D}) \mathcal{S}$, the corresponding auxiliary coefficients can be written as $\psi_S \mathcal{S}$ and furthermore $\psi_0, S' = 0$ as $\psi$ is the set of valid moments. Given some constant $C_0 = (0, 1)$, define $M_{\psi}^* = I \cup D_{\psi}^*$ with $D_{\psi}^* = \{j \in \mathcal{D} : |\xi_i^j(T)(\psi)| \geq C_0 \nu_2^j(0^+))$. We assume the existence of a sequence $\ell_n \to \infty$ such that
\[
\begin{align*}
\mathbb{P} \left( \max_{\psi \in \Psi : \psi_S = \theta, 0, S' \geq \varepsilon, |\psi_S| \leq \varepsilon, |\psi_S| \leq \varepsilon, |\ell_n^T(\psi) - \ell_n| \leq \varepsilon \right) & \to 1
\end{align*}
\]
with some $c_n \gg \phi_n$.

Let $b_{1,n} = \max\{a_n, r_1 n^2\}$ and $b_{2,n} = \max\{b_1 n, b_2 n^2\}$. Then $\phi_n = \max\{b_{1,n}, b_{2,n}\}$. Define $\Psi_\ast = \{\psi : (\psi_S, \psi^T_S)^T : |\psi_S| \leq \varepsilon, |\psi_S| \leq \varepsilon, \}$. For any $\varepsilon > 0$.

Consider
\[
\hat{\psi} = \arg \min_{\psi \in \Psi, \ast \in \mathcal{A}} \mathbb{E}_{\psi}[\{\xi_i^2(T)(\psi)\}^2]
\]

Proposition 3.1 shows that such a $\hat{\psi}$ is a sparse local minimizer for (3.1).

**Proposition 3.1.** Let $P_{1,\pi}(\cdot), P_{2,\pi}(\cdot) \in \mathcal{P}$ for $\varphi$ defined in (3.2), and $P_{2,\pi}(\cdot)$ be convex with bounded second derivative around 0. For $\varphi$ defined as (3.7), assume there exists a constant $\tilde{\varepsilon} \in (C_a, 1)$ such that $\mathbb{P}[\cup_{j \in \mathcal{T}} \{\xi_i^2(T)(\psi)\}] \in [\varepsilon \nu_2^j(0^+), \nu_2^j(0^+)]$.

Under Conditions 1–4 and (3.6), if $|\log r| = o(n^{1/2})$, $s^2 \varepsilon_n \phi_n^2 = o(1)$, $b_{2,n} = o(n^{-2/3})$, $\ell_n = o(\varepsilon)$, and $\ell_n \geq \varepsilon$, then with probability approaching one this $\hat{\psi} = (\theta^T, \varepsilon_\ast^T, \psi^T_S)^T$ provides a sparse local minimizer for the nonconvex optimization (3.1) such that (i) $|\hat{\theta} - \theta_0| = O_p(\nu_2^j(0^+))$, (ii) $\tilde{\varepsilon}_{\ast} - \xi_{0,\ast} \leq |\varepsilon_n| = O_p(\phi_n)$, and (iii) $\mathbb{P}(\hat{\varepsilon}_{\ast} = 0) \to 1$ as $n \to \infty$.

In the rest of this section, we focus on the sparse local minimizer $\hat{\psi}_{\text{PEL}} = (\hat{\theta}_{\text{PEL}}^T, \varepsilon_{\text{PEL}}^T)^T$ specified in (3.7). We proceed with additional regularity conditions.

**Condition 5.** There exists a universal constant $K_5 > 1$ such that $K_5^{-1} < \lambda_{\min}(Q_{T, \mathcal{D} \mathcal{B}_1 \mathcal{B}_2}^T) \leq \lambda_{\max}(Q_{T, \mathcal{D} \mathcal{B}_1 \mathcal{B}_2}^T) < K_5$ for any $\mathcal{B}_2 \subset \mathcal{B}_1 \subset \mathcal{D}$ with $p + |\mathcal{B}_2| \leq 1 + |\mathcal{B}_1| \leq \ell_n$, where $Q_{T, \mathcal{D} \mathcal{B}_1 \mathcal{B}_2} = (\mathbb{E}[\psi_{p, \mathcal{D} \mathcal{B}_1 \mathcal{B}_2}^T \xi_{0, \mathcal{D} \mathcal{B}_1 \mathcal{B}_2}])^T\hat{\psi}_{\text{PEL}}$.

**Condition 5** is the sparse Riesz condition (Zhang and Huang 2008; Chen and Chen 2008) in our setting to deal with the high-dimensional $\psi$ when $p + r_2 > n$. Let $\hat{\lambda}(\hat{\psi}_{\text{PEL}})$ be the $r \times 1$ vector.
Remark 2. Notice that \( a_n \lesssim s \tau \). To satisfy the restrictions in Theorem 3.1, it is sufficient for \((n,r,p,\ell_n,s)\) to have: \( r = o(\exp(n^{1/3})) \), \( \ell_n = o(n^{(r-2)/3}) \), \( \ell_n^{3/2}s^{3/2}(\log r)^{-3} \), the tuning parameters \( v \) and \( \pi \) satisfying \( \ell_n^{1/2}n_s \ll \pi \ll \min\{s^{-1}n^{-2/3}, \ell_n^{-4}s^{-4}p^{-2} \} \), \( \ell_nN_n \ll v \ll \min\{\ell_n^2p^2, (\ell_n^3n_s)^{-1/4}, (\ell_n^2n_s^2)^{-1/4} \} \) and \( v^2 \pi \ll (\ell_n^2n_s^4p^{-2})^{-1} \).

Thanks to the extra valid moments in \( g^{(D)} \), the asymptotic covariance of \( \hat{\theta}_{PEL} \) is smaller than that of \( \hat{\theta}_{EL}^{(Z)} \) which uses the information in \( g^{(Z)} \) only. On the other hand, given that \( \hat{\theta}_{EL}^{(Z)} \) provides asymptotic normality under the set of correctly specified moments \( I \), one may question whether it is worthwhile to consider all the available moments among which some may risk misspecification. This is a tradeoff between robustness and efficiency, a recurrent theme in modern econometrics. Although it inevitably depends on the data generating process (DGP), in big data environments the efficiency gain may be substantial. Benefits are demonstrated in the simulation exercises and the empirical application via very simple econometric models. \(^4\)

Remark 3. The setting with the sets \( I \) and \( D = A \cup A^c \) is the same as Liao (2013). When estimating (2.3) with low-dimensional moments based on GMM, Cheng and Liao (2015) require the number of estimating functions \( r = o(n^{1/3}) \), and the signal of invalid estimating functions \( \min_{k \in A^c} \mathbb{E}[g_{k,D}^{(D)}(\theta_0)] \gg (rn^{-1})^{1/2} \). Our conditions on the relative size of the dimensions are more general. A sufficient condition for (3.6) is \( \min_{k \in A^c} \mathbb{E}[g_{k,D}^{(D)}(\theta_0)] \gg \max\{v, p(s \tau)^{1/2}, p \ell_n^{-1}n_s \} \), in view of \( a_n \lesssim s \tau \). Under the restrictions discussed in Remark 2, if we select \( v \) and \( \pi \) sufficiently close to \( \ell_nN_n \) and \( \ell_n^{-2}n_s^{-1} \), respectively, then (3.6) holds provided that \( \min_{k \in A^c} \mathbb{E}[g_{k,D}^{(D)}(\theta_0)] \gg p \ell_n^{-1/2}n_s^{-1}n_s \). This is similar to the “beta-min condition” which is necessary for consistent variable selection by shrinkage methods (Bühlmann 2013).

Remark 4. Under low-dimensional moments the asymptotic normality involves no bias; see Liao (2013, Theorem 3.5) and Cheng and Liao (2015, Theorem 3.3). In contrast, Theorem 3.1 here makes clear that the high-dimensional moments incur an additional asymptotic bias \( \hat{\xi}_{R_n(1)} \). To conduct hypothesis testing or construct confidence region about \( \theta \), in principle we can estimate and correct the bias \( \hat{\xi}_{R_n(1)} \). Such a direct bias correction approach, nevertheless, is undesirable in practice and in theory. The bias term involves multiplication and inverse of large matrices, which are difficult to estimate with precision in finite samples. Illustrated in our simulation experiments in Section 6, we are unsatisfied with the asymptotic normality approximation after estimating and correcting the bias. Thus, we view Theorem 3.1 as a characterization of the asymptotic behavior of \( \hat{\theta}_{PEL} \), but we do not encourage carrying out statistical inference based on it. Instead, Section 5 recommends PPEL for inference.

\(^4\)See the RMSEs in Table 2, the length of confidence intervals in Figure 2, and the standard deviations in Table 4.
While the augmented parameter $\xi$ essentially validates all moments in $D$, the efficiency gain comes from the penalty on $\xi$ that shrinks some $\hat{\xi}_k$, $k \in A$, to zero, thereby confirming the validity of these associated moments. To discuss moment selection, we write $\hat{\xi}_{PEL} = (\hat{\xi}_k)_{k \in D}$. If all valid estimating functions in $A$ are selected by the optimization (3.1), that is, $\hat{\xi}_k = 0$ for all $k \in A$, then the asymptotic covariance of $\hat{\theta}_{PEL}$ is $(J(\theta_{PEL}))^{-1}$.

Remind that $(J(\theta_{PEL}))^{-1}$ in Proposition 2.1 is the semiparametric efficiency bound for the estimation under the oracle, and Proposition 3.1 shows that $P(\hat{\xi}_{PEL,A} = 0) \to 1$ as $n \to \infty$, which provides a natural moment selection criterion

$$\hat{A} = \{k \in D : \hat{\xi}_k = 0\}$$

(3.9)
to identify the valid estimating functions in $A$. Notice that Proposition 3.1 also indicates that $|\hat{\xi}_{PEL,A}^\top - \xi_{0,A}^\top|_\infty = O_p(n)$. Together with (3.6), we have $P(\cup_{k \in A^c} [\hat{\xi}_k = 0]) \to 0$ as $n \to \infty$. Based on these arguments, Theorem 3.2 supports our proposed moments selection criterion.

**Theorem 3.2.** Under the conditions of Proposition 3.1, it holds that $P(\hat{A} = A) \to 1$ as $n \to \infty$.

Up to now, we have established the asymptotic properties of the PEL estimator for the moment-defined model (2.3) with high-dimensional moments and low-dimensional $\theta$. The next section further extends the estimation to a high-dimensional structural parameter.

### 4. High-Dimensional Moments with High-Dimensional $\theta$

A high-dimensional parameter $\theta$ is present when many control variables are included in the structural model. For example, the leading case of the linear IV model takes only one endogenous variable and it is accompanied by a few corresponding IVs. Nevertheless, such a simple setting may still involve many exogenous control variables in the main equation, and these control variables are natural instruments for themselves. An empirical example can be found in Blundell, Pashardes, and Weber (1993). Fan and Liao (2014) propose the focused GMM for such a linear IV model, which is a special case of the moment-defined model.

In this section, $p$ and $r_{2}$ are both allowed to be much larger than $n$, whereas $r_{1}$ is fixed or diverges at some slow polynomial rate of $n$. We assume $\theta_0$ sparse in the sense that most of its components are zero. Write $\theta_0 = (\theta_{0,l})_{l \in P}$ and define the active set $P_2 = \{l \in P : \theta_{0,l} \neq 0\}$ with cardinality $p_2 = |P_2|$. To obtain a sparse estimate of $\theta_0$, we add to (3.1) a penalty on $\theta$ to produce the following optimization problem:

$$\begin{align*}
\hat{\theta}_{PEL}, \hat{\xi}_{PEL} & = \arg\min_{\theta \in \mathbb{R}^p} \max_{\Psi \in \Psi(A)} \left[ \frac{1}{n} \sum_{i=1}^{n} \log(1 + \eta^\top \mathbf{g}_i(\Psi)) \\
& - \sum_{j \in D} P_{2,s}(\lambda_j) + \sum_{k \in D} P_{1,s}(\lambda_k) \\
& + \sum_{l \in P} P_{1,s}(\phi_l) \right].
\end{align*}$$

(4.1)

With slight abuse of notation, we keep using $(\hat{\theta}_{PEL}^\top, \hat{\xi}_{PEL}^\top)^\top$ to denote the solution to (4.1).

As $p$ can be bigger than $r_1$ in high dimension, here we update Condition 1 for the identification of $\theta_0$. In view of Chang, Tang, and Wu (2018), we impose Condition 1′ for the identification of the nonzero components of $\theta_0$.

**Condition 1′.** (i) There exists a universal constant $K_1' > 0$ such that

$$\inf_{\theta \in \Theta} \mathbb{E} [\|\mathbf{g}(\theta)\|_\infty] \geq K_1' \varepsilon$$

for any $\varepsilon > 0$. (ii) There exists a universal constant $K_3' > 0$ such that $sup_{\theta \in \Theta} \mathbb{E} [\|\mathbf{g}(\theta)\|_{\infty}] \leq K_3'$.

As we have shown in Section 3, the index set $S$ and the quantities $a_n$ and $\phi_n$ play key roles in the theoretical analysis of the low-dimensional $\theta$ in (3.1). Under the current high-dimensional setting, we define

$$a_n = \sum_{k \in D} P_{1,s}(\lambda_k) + \sum_{l \in P} P_{1,s}(\phi_l)$$

and

$$S = P_2 \cup A^c \quad \text{with} \quad s = |S|.$$  

(4.2)

This $S$ indexes all nonzero components in the true augmented parameter $\psi_0$. Compared to its counterpart $a_n$ in Section 3, the newly defined $a_n$ here is amended with an extra term $\sum_{l \in P} P_{1,s}(\phi_l)$ due to the penalty imposed on $\theta$. In the current high-dimensional setting, we also redefine

$$\phi_n = \max\{p_2 a_1^{1/2}, p_2^{1/2} \kappa_{n,v}\}$$

(4.3)

with $a_n$ in (4.2). To control the bias introduced by $P_{1,s}(\cdot)$ on $\hat{\theta}_{PEL}$ and $\hat{\xi}_{PEL}$, similar to (3.6), we assume that among the elements in $\psi_0 = (\psi_{0,1}, \ldots, \psi_{0,p+r_2})^T$, the minimal active signal is

$$\min_{k \in S} |\psi_{0,k}| \gg \max_{k \in S^c} |\psi_{0,k}|$$

(4.4)

with $\phi_n$ in (4.3) and $\max_{k \in S} \sup_{c \in [c_{\psi_{0,k}} - c_{\psi_{0,k}} - 1]} |\psi_{0,k}|P_{1,s}^T c = 0$ for some constant $c \in (0, 1).$ Given the newly defined $S$ and $\phi_n$, we can further update $\ell_n, R_n, A_{n,v}, A_{n,c}$ and $T^*$ in the same manner as their counterparts in Section 3. Moreover, we also define $\ell_{R_n}^T$ and $\hat{\xi}_{R_n}$ as specified in Section 3 with $S_n = P_2 \cup A_{n,c}$. For any $\psi \in \Psi$, we have $\psi_{S_n} = (\hat{\theta}_{PEL}^T, \hat{\xi}_{PEL}^T)^T$.

Proposition A.2 in the supplementary materials shows that there exists a sparse local minimizer \( (\theta_{PEL}^*, \xi_{PEL}^*)^T \in \Psi \) for the nonconvex optimization (4.1) such that $P(\theta_{PEL}^*, \xi_{PEL}^*) = 0 \to 1$ as $n \to \infty$, which means all zero components of $\theta_0$ can be estimated exactly as zero with high probability. The limiting distribution of such $\theta_{PEL}^*$ and the moment selection outcomes are stated in Theorem 4.1.

**Theorem 4.1.** Let $P_{1,s}(\cdot), P_{2,s}(\cdot) \in \mathcal{P}$ for $\mathcal{P}$ defined in (3.2), and $P_{2,s}(\cdot)$ be convex with bounded second derivative around 0. For the sparse local minimizer $\psi_{PEL} = (\hat{\theta}_{PEL}^T, \hat{\xi}_{PEL}^T)^T$ for
parameter, without loss of generality, we write \( \theta = (\theta_{0, p_z}, 0^T)^T \) and the inverse of \( \mathbf{I}_T^{(T)} \) in Theorem 3.1 in the following compatible partitioned matrix

\[
\mathbf{I}_T^{(T)} = \begin{bmatrix}
(\mathbf{I}_T^{(T)})^{-1}_{11} & (\mathbf{I}_T^{(T)})^{-1}_{12} \\
(\mathbf{I}_T^{(T)})^{-1}_{21} & (\mathbf{I}_T^{(T)})^{-1}_{22}
\end{bmatrix},
\]

where \( (\mathbf{I}_T^{(T)})^{-1}_{11} \) is a \( p_z \times p_z \) matrix. The asymptotic covariance of \( \hat{\mathbf{I}}_{p_z, p_z} \) by (3.1) is \( (\mathbf{I}_T^{(T)})^{-1}_{11} \), and that in (4.1) is \( \mathbf{W}_T^{(T)} \) according to Theorem 4.1. Notice that \( \mathbf{W}_T^{(T)} = \mathbf{I}_T^{(T)} - 2 \mathbf{W}_T^{(T)} \mathbf{I}_T^{(T)} - 1 \mathbf{I}_T^{(T)} \) by the inverse of a partitioned matrix. Implicitly restricting the parameter space, the penalty on \( \theta \) gains efficiency for the estimation of \( \theta_{0, p_z} \), the nonzero components of \( \theta_0 \).

Remark 6. Theorem 4.1 spells out the limiting distribution and efficiency gain for the estimator of the nonzero components in \( \theta_0 \). If one is interested in some coefficient in \( P_{p_z}^c \), we have consistency in that \( \mathbb{P}(\hat{\mathbf{I}}_{p_z, p_z} = 0) \to 1 \) as \( n \to \infty \), but the limiting distribution is irregular due to the shrinkage. Furthermore, parallel to Remark 3.1 the asymptotic bias is again present. Similar to Remark 4, we do not suggest conducting statistical inference predicated on this characterization of the asymptotic behavior of normality.

Statistical inference is important in applied econometrics when researchers intend to assess whether the estimated result supports or rejects a hypothesized value of the parameter. The next section proposes an inferential procedure based on a projection of estimating functions, which is free of asymptotic biases.

5. Confidence Regions for a Subset of \( \psi \)

Suppose we are interested in the inference for a subset of parameters \( \psi_M \) for some generic small subset \( M \subset (P \cup D) \) with \( |M| = m \). Here we allow \( m \) to be fixed or diverge slowly with the sample size \( n \). What is novel here is that \( \psi_M \) is allowed to contain part of the auxiliary parameter \( \xi \), for which our method will provide a formal statistical inference for the validity of a subset of the high-dimensional moment restrictions. In contrast, Liao (2013) offers asymptotic normality for the structural parameter \( \theta \) under low-dimensional moments but does not characterize the asymptotic distribution of the auxiliary parameter \( \xi \).

A key technical issue is how to deal with the high-dimensional nuisance parameter \( \psi_M^c \), where \( M = (P \cup D) \setminus M \). Our approach follows Chang et al. (2021) to project out the influence of the nuisance parameter. Such idea was also used in Ning and Liu (2017) and Neykov et al. (2018). Given an initial estimate \( \psi^* \) for \( \psi_0 \), we first determine a linear transformation matrix \( A = \begin{bmatrix} a_0^T & I_{k \times M} \end{bmatrix}^T \in \mathbb{R}^{m \times m} \) with each row defined as

\[
a_{kj} = \arg \min_{u \in \mathbb{R}^r} |u_1| \quad \text{s.t.} \quad |\nabla_{\psi} g^{(T)}(\psi^*)^T u - y_k|_\infty \leq \xi
\]

for \( k \in M \), where \( \xi \to 0 \) as \( n \to \infty \) is a tuning parameter, and \( \{y_{kj}\}_{k \in M} \) is a basis of the linear space \( b = \begin{bmatrix} y_{kj} \end{bmatrix}_{k \in M} : b_{M'} = 0 \). In practice, we can specify the \( (p + r_z) \)-dimensional vector \( y_k = \{1(\xi = k)\}_{k \in M} \) with all zero elements except one unit entry. As we will discuss in Remark 8, the solution from (3.1) or (4.1) can serve as the initial estimator \( \psi^* \).

Based on \( A \) as in (5.1), we then obtain the new \( m \)-dimensional estimating functions \( f_{A_n}(\cdot ; \cdot) \) by projecting \( g^{(T)}(\cdot ; \cdot) \) on \( A_n \):

\[
f_{A_n}(X; \psi) = A_n g^{(T)}(X; \psi).
\]

Write \( y_k = \{y_{kj}\}_{k \in M} \) and define an \( m \times (p + r_z) \) matrix \( \Gamma = \{y_{kj}\}_{k \in M, j \in P \cup D} \). The definition of \( A_n \) implies that \( |\nabla_{\psi} f_{A_n}(\psi^*) - \Gamma|_\infty \leq \xi \). Since all the components in the \( j \)-th column of \( \Gamma \) are zero for \( j \in M' \), the newly defined estimating functions \( f_{A_n} \) is uninformative of the nuisance parameter \( \psi_{M'} \). Informative is \( f_{A_n} \) of the parameter \( \psi_M \) of interest, as for \( j \in M \), some components in the \( j \)-th column of \( \Gamma \) must be nonzero.

Given the projected estimating functions \( f_{A_n} \), it is possible to directly borrow from Chang et al. (2021) to construct the confidence region of \( \psi_M \) by the EL ratio

\[
w_n(\psi_M) = \max_{\lambda \in \tilde{\Lambda}_n(\psi_M)} \sum_{i=1}^n \log(1 + \lambda^T f_{A_n}^i(\psi_M, \psi_M^*))
\]

with respect to \( \psi_M \), where \( \tilde{\Lambda}_n(\psi_M) = \{\lambda \in \mathbb{R}^n : \lambda^T f_{A_n}(\psi_M, \psi_M^*) \in \mathcal{V} \forall i \in [n]\} \). Since \( w_n(\hat{\psi}_M) \xrightarrow{d} \chi_m^2 \) as \( n \to \infty \) for a fixed \( m \), the set \( \psi_M \in \mathbb{R}^n : \lambda^T f_{A_n}(\psi_M, \psi_M^*) \in \mathcal{V} \forall i \in [n] \).
$w_n(\psi_{M}) \leq \chi^2_{m_1, 1 - \alpha}$ provides a 100(1 - $\alpha$)% confidence region for $\psi_{M}$, where $\chi^2_{m_1, 1 - \alpha}$ is the (1 - $\alpha$)-quantile of $\chi^2_{n}$ distribution. Nonetheless, the finite-sample performance of such an asymptotically valid confidence region depends crucially on the convexity of $w_n(\psi_{M})$ near $\psi_{0,M}$. If convexity fails in a finite sample, this EL-ratio-based confidence region will be voluminous in magnitude due to numerical instability. Verifying the convexity condition is onerous, in particular when $m$ is large, for $f^A_n(\psi_{M}, \psi^*_{M})$ may be a nonlinear function of $\psi_{M}$.

To secure a stable confidence region for $\psi_{M}$, in this article we deviate from Chang et al. (2021) and instead recommend a re-estimation procedure for a confidence region based on the asymptotic normality of the estimator. Let

\[
\tilde{\psi}_{M} = \arg \min_{\psi_{M} \in \mathcal{M}} \max_{\kappa \leq \mathcal{A}(\psi_{M})} \sum_{i=1}^{n} \log[1 + \lambda^T f^A_i(\psi_{M}, \psi^*_{M})],
\]

where $\psi^*_{M} = \{ \psi_{M} : |\psi_{M} - \psi^*_{M}| \leq O_p(\sigma_{1,n}) \}$ for some $\sigma_{1,n} \to 0$ such that $|\psi_{M} - \psi^*_{0,M}| = O_p(\sigma_{1,n})$. Since $\psi^*_{M}$ is an initial consistent estimator of $\psi^*_{0,M}$, it is reasonable to search for $\tilde{\psi}_{M}$ in a small neighborhood of $\psi^*_{M}$. We will specify $\sigma_{1,n}$ for some specific choices of $\psi^*_{M}$ in Remark 8.

To derive the limiting distribution of $\tilde{\psi}_{M}$, we assume the following condition.

**Condition 7.** For each $k \in \mathcal{M}$, there is a nonrandom $a_k$ satisfying $E[\nabla^2 \tilde{g}_k(\psi^*)]a_k = \gamma_k$, $|a_k|_1 \leq K_0$ for some universal constant $K_0 > 0$, and $\max_{\kappa \in \mathcal{A}(\psi_{M})} |a_k - \hat{a}_k|_1 = O_p(\omega_n)$ for some $\omega_n \to 0$. Let $A_k = (a_k)^T \kappa \in \mathbb{R}^{m \times r}$. The eigenvalues of $A^{\otimes 2}$ are uniformly bounded away from zero and infinity.

**Remark 7.** Let $\Xi = E[\nabla^2 \tilde{g}_k(\psi^*)]$ and $\tilde{\Xi} = \nabla^2 \tilde{g}_k(\psi^*)$. It follows from the existence of $a_k$ that $\gamma_k = \Xi^{-1} a_k + (\Xi - \tilde{\Xi}) a_k = \tilde{\Xi} a_k + e_k$, where $e_k = (\Xi - \tilde{\Xi}) a_k$. Some mild conditions ensure $|\Xi - \tilde{\Xi}|_\infty = O_p(1)$. This, together with the assumption $|a_k|_1 \leq K_0$, implies that $e_k$ is stochastically small uniformly over all the components such that $|e_k|_\infty = O_p(1)$, which can be viewed as an attempt to recover a nonrandom $a_k$ with no noise asymptotically (Candes and Tao 2007; Bickel, Ritov, and Tsybakov 2009). It follows that $|a_k - \hat{a}_k|_1 = O_p(1)$ if $\tilde{\Xi}$ satisfies the routine conditions for sparse signal recovering. Furthermore, the constant $K_0$ in Condition 7 may be replaced by some diverging $\varphi_n$, and our main results remain valid.

Theorem 5.1 gives the limiting distribution of $\tilde{\psi}_{M}$ with a generic initial estimator $\psi^*$. The above theorem is stated for $\tilde{\psi}_{M}$. It includes the estimation of $\theta_{M}$ as a special case if one’s research interest falls on the main parameter for econometric interpretation, and makes it possible to infer the validity of a subset of moments in view of selecting $\tilde{\psi}_{M} = \xi_{M}$.

**Remark 8.** We verify that the PEL estimator is qualified to serve as $\psi^*$ in Theorem 5.1. Define $s = |S \cap M|$, and thus $|S \cap M| = s - s$. If $\theta_{0}$ is low-dimensional and we choose $\psi^* = \psi_{PEL}$ in (3.1), we have $\sigma_{1,n} = \tilde{s} \sigma_n$ and $\sigma_{2,n} = (s - s) \sigma_n$ due to $|\psi_{PEL,s} - \psi_{0,s}|_\infty = O_p(\phi_n)$ and $\mathbb{P}(|\psi_{PEL,s} - \psi_{0,s}|_\infty = 0) \to 1$. Then $m \sigma_{1,n} = o(1)$ and $\sigma_n^2 = o(1)$, $\sigma_n^2 = o(1)$, and $\sigma_n^2 = o(1)$, the asymptotic normality of Theorem 5.1 holds under this choice of the initial value $\psi^* = \psi_{PEL}$. Analogously, if $\psi^* = \psi_{PEL}$ in (4.1) then $\theta_{0}$ is of high dimension, Theorem 5.1 also holds provided that $m, \sigma_n$, and $\zeta$ satisfy the same restrictions with the newly defined $s$ and $\phi_n$ in Section 4.

So far, we have established statistical inference results based on the PPEL estimator $\tilde{\psi}_{M}$ when we are interested in a small subset $\mathcal{M}$ of $\psi$. In the next section, we check the finite sample performance via simulations.

### 6. Numerical Studies

One of the most important models in econometrics is the linear IV regression. We design a linear IV model here to mimic the empirical application in Section 7, whereas simulation results of a nonlinear panel regression with time-varying individual heterogeneity are presented in the supplementary materials.

Suppose that the researcher has at hand a dataset of $n$ independent observations of a vector $(y_i, z_{i1}, z_{i2}, w_{i1}, w_{i2})$, and $y_i$ is estimated in the main structural equation

$$y_i = \beta_{1} x_{i1} + \beta_{2} z_{i2} + \xi_i,$$

where $x_i$ is a scalar endogenous variable, and $z_i$ is a $d_c \times 1$ vector of exogenous variables (including the intercept). Such an equation with a scalar endogenous variable is the leading case of IV regressions (Andrews, Stock, and Sun 2019). Due to space limitations, we report the results when we specify $z_i = (1, z_{i1}, z_{i2})^T \in \mathbb{R}^3$ with $z_{i1}, z_{i2} \sim \mathcal{N}(0, 1)$, and the coefficients $(\beta_{1}, \beta_{2})^T = (0.5, 0.5, 0.5)^T$ in a plausible setting. The numerical performance are robust across our experiments when the parameters are varied.

The corresponding reduced-form equation is $x_i = \gamma_{w1} w_{1i} + \gamma_{w2} w_{2i} + \gamma_{z1} z_{i1} + u_i$, where $w_{1i} \in \mathbb{R}$ and $w_{2i} \in \mathbb{R}^{d_w}$ are included instruments. We specify $(w_{1i}, w_{2i})^T \sim \mathcal{N}(0, I_{d_w})$. $\gamma_{w1} = 0.8$, $\gamma_{w2} = (\gamma_{w2})_{i \in [d_w]}$ with $\gamma_{w2} = 0.4 - 0.3(1 - (4d_w - 1))$, and $\gamma_{z1} = (0.8, 0.8, 0.8)^T$. The two error terms $(\epsilon_{i}, u_{i})^T$ are generated from the two-dimensional normal distribution with mean 0, covariance matrix and correlation 0.5 which are independent of $(z_{i1}, z_{i2}).$ An additional vector $w_{3i} = (w_{3i} j)_{i \in [d]} \in \mathbb{R}^r$, which serves as the invalid IV, follows $w_{3i} j \sim \mathcal{N}(0, 1)$ independent of $(\epsilon_{i}, u_{i})$, and $\delta_{i} \neq 0$ controls the strength of correlation. Write $\delta = (\delta_{i})_{i \in [d]}$. To emulate the
scenarios of weak, moderate, and strong correlations between $\epsilon_i$ and $w_{ij}$, we set $\delta_j = 0.3 + 0.2(j-1)/(s-1)$, $0.5 + 0.2(j-1)/(s-1)$ and $0.7 + 0.2(j-1)/(s-1)$, respectively. It is expected that the smaller is the coefficient, the less severe is misspecification, so estimation is more prone to selection mistakes in finite samples.

While the researcher is confident about the validity of $w_{1i}$ in that $g_i^T(\theta) = (w_{1i}, z_i^T \times (y_i - \beta s x_i - \beta z_i^T z_i))$, where $z_i$ is self-instrumented, she is uncertain about the validity of $(w_{2i}, w_{3i})$ and therefore must detect the invalid IVs. The two classes of undetermined (to the researchers) IVs consist of $g_i^T(\theta) = (w_{2i}, w_{3i})^T \times (y_i - \beta s x_i - \beta z_i^T z_i)$. According to our DGP design, $w_{3i}$ is the valid IV vector so the moments involving $w_{3i}$ equal to zero under the true parameter; those moments involving $w_{2i}$ are invalid.

Let $d_w = d_{w_2} + s + 1$ be the number of all the IVs, among which $s$ IVs are invalid. In the low-dimensional setting, we fix $s = 6$ and consider $(n, d_w) = (100, 50)$ or $(200, 100)$. In the high-dimensional setting, we vary the number of invalid IVs to be $s \in \{6, 8, 13\}$ for $(n, d_w) = (100, 120)$, and $s \in \{6, 12, 17\}$ for $(n, d_w) = (200, 240)$, where $s$ is specified by rounding, in addition, $2 \log n$ and $3n^{1/3}$.

In terms of the numerical implementation, we compute the PEL estimates by the modified two-layer coordinate descent algorithm (Chang, Tang, and Wu 2018). The SCAD penalty is used for both $P_{1s}(\cdot)$ and $P_{2s}(\cdot)$ in (3.1) for all the numerical experiments in this article with local quadratic approximation (Fan and Li 2001), and the tuning parameters $\nu$ and $\tau$ are chosen by the Bayesian information criterion (BIC). Specifically, we use the following BIC type function:

$$
\text{BIC} = \ell(\hat{\psi}_{\text{PEL}}) + (\log n) \cdot \text{df}(\hat{\psi}_{\text{PEL}}),
$$

where $\text{df}(\hat{\psi}_{\text{PEL}})$ denotes the number of nonzero elements in $\hat{\psi}_{\text{PEL}}$, and the log likelihood term is the EL ratio $\ell(\hat{\psi}_{\text{PEL}}) = 2 \sum_{i=1}^n \log \left(1 + \hat{\lambda}(\hat{\psi}_{\text{PEL}})^T \hat{g}_i^T(\hat{\psi}_{\text{PEL}})\right)$.\(^7\)

We first report results of moment selection by our selection criterion in (3.9). Let “FP” (false positive) denote the frequency that the valid moments being not selected, and “FN” (false negative) denote the frequency that the invalid moments being selected. In Table 1, PEL and DB-PEL denote the moment selection criterion based on the PEL estimator and its de-biased version, respectively. As expected, the strength of correlations between $\epsilon_i$ and $w_{3i}$ does not affect FP, whereas FN quickly vanishes as the correlations get stronger. In all cases, larger sample sizes help reduce the chance of moment selection error.

The parameter of interest in the linear IV model is $\beta$ in (6.1) as it characterizes the “causal effect” of the endogenous variable, which bears economic interpretation. The root-mean-square error (RMSE), bias (BIAS) and standard deviation (STD) are calculated for PEL, DB-PEL and the classical two-stage least squares (2SLS) for (6.1), and an oracle estimator is added for comparison.\(^8\) The results are summarized in Table 2. The performance of PEL and the oracle is comparable, and the gaps are narrowed when the sample size is increased from $n = 100$ to $n = 200$, suggesting the capacity for PEL to mimic the oracle by absorbing the signal from the valid moments and in the meantime keeping the invalid ones at bay. The RMSE of 2SLS is significantly larger than those of PEL and DB-PEL.

The left panel of Figure 1 plots the empirical cumulative distribution functions (ECDF) of the DB-PEL estimates. The dotted curve corresponds to the case of $(n, d_w, s) = (100, 120, 8)$, the dashed curve to that of $(n, d_w, s) = (200, 240, 12)$, and the solid curve is the cumulative distribution function (CDF) of $\mathcal{N}(0,1)$ for comparison. A better normal approximation can be obtained by the PPEL estimate, as shown in the right panel of Figure 1, with its tuning parameter $\zeta = 0.08(n^{-1} \log p)^{1/2}$. We also present the confidence intervals (CI) according to PPEL, DB-PEL and 2SLS, as reported in Table 3, for the 90%, 95% and 99% levels, where the CIs for DB-PEL and PPEL are predicated on the asymptotic normality from Theorems 3.1 and 5.1, respectively, and the CIs for 2SLS are based on its asymptotic normality as in standard textbooks. PPEL’s coverage probability to the nominal counterpart is the best among the three estimators, and is much better than PEL. 2SLS’s coverage probability seems too high in the high-dimensional setting, though it is acceptable in the low-dimensional case. Figure 2 shows that the width of 2SLS’s CI is much wider than that of PPEL, which is caused by efficiency loss from abandoning the potentially valid estimating equations.

### 7. Empirical Application

Colonialism was widespread over the globe prior to the Second World War. While European institutions which protected private properties and checked government powers were successfully replicated in a few colonies, many others suffered expropriation of natural and human resources. In an influential study, Acemoglu, Johnson, and Robinson (2001) (AJR, henceforth) systematically explored the relationship between Europeans’ mortality rates and the modes of institutions.

---

\(^7\)Leng and Tang (2012) employ this BIC to choose the tuning parameter for the high-dimensional parameter $\hat{\phi}$, and Chang, Tang, and Wu (2018) apply it to select multiple tuning parameters. We follow their practice as (6.2) remains valid in our setting where two tuning parameters are included.

\(^8\)The oracle EL in Section 2.2 is for low-dimensional parameters and moments. To handle the large pool of orthogonal IVs, the oracle estimator here is a 2SLS estimator taking advantage of a few most relevant IVs—those with the top 0.1n big coefficients $\hat{\psi}_w$ in the reduced-form equation.

---

**Table 1. PEL’s performance in moment selection.**

| $(n, d_w, s)$ | Correlation: | Weak | Moderate | Strong |
|--------------|-------------|------|---------|--------|
|               | method      | FP   | FN      | FP     | FN     |
| (100, 50, 6)  | PEL         | 0.1995 | 0.0267 | 0.1933 | 0.0003 | 0.2359 | 0.0000 |

We revisit AJR’s open-access dataset. AJR’s main structural equation is $y_i = \gamma y + \beta x_i + \beta z_i + \epsilon_i$, where the dependent variable $y_i$ is logarithm GDP per capita in 1995, and the key explanatory variable of interest $x_i$ is average protection against expropriation risk, a continuous variable of a scale between 0 and 10. The latitude of a colony, denoted as $z_i$, is an additional control variable. For substantial measurement errors in the institutional index $x_i$ can bias the OLS estimator, the credibility of the empirical evidence counts on IVs. AJR compiled from historical documents a seminal variable logarithm of European settler mortality, and argued forcefully that it qualifies as a valid IV for the endogenous variable $x_i$. Their empirical evidence was based on the 2SLS regression in cross-sectional data of countries. The baseline result in AJR’s Column (2) of Table 4 (p.1386)
Table 3. Coverage probabilities for the CI of $\beta_x$.

Panel A: low-dimensional setting

Panel B: high-dimensional setting

Figure 2. Width of 90% (left), 95% (middle), and 99% (right) CI for $\beta_x$ estimated by PPEL, DB-PEL, and 2SLS under moderate correlation between $\epsilon_i$ and $w_3i$ with $(n, dw, s) = (100, 120, 8)$.

corresponds to the three estimating functions $g^{(l)}_i(\theta) = (w_{1i}, z_i, 1)^T \times (y_i - \gamma y - \beta_{xx} x_i - \beta_{x}z_i)$ by the notations in our simulation, and the 2SLS reports $\hat{\beta}_x = 1.00$ with STD 0.22.

There are another 11 potential health variables and institutional variables, which serve as potential IVs. AJR were uncertain about their validity, and they experimented in their Table 7 (p.1392) and Table 8 (p.1394) the empirical results under various IV configurations. These variables, denoted as $w_2$, are (i) Malaria in 1994, (ii) Yellow fever, (iii) Life expectancy, (iv) Infant mortality, (v) Mean temperature, (vi) Distance from coast, (vii) European settlements in 1990, (viii) Democracy (1st year of independence), (ix) Constraint on executive (1st year of independence), (x) Democracy in 1900, and (xi) Constraint on executive in 1900. (i)–(iv) are health variables, (v)–(vi) are geographic variables, and (vii)–(xi) are institutional variables. All these extra IVs are associated with the estimating functions $g^{(l)}_i(\theta) = w_2i \times (y_i - \gamma y - \beta_{xx} x_i - \beta_{x}z_i)$. Given the moderate sample size of 56 countries, a total of 12 IVs is nontrivial.
Table 4. Estimation of the effect of institution ($\beta_\zeta$).

| $\zeta$ | PE  | STD  | 95% CI       |
|---------|-----|------|-------------|
| PEL     | NA  | 0.937| 0.078 (0.786, 1.090) |
| DB-PEL  | NA  | 0.938| 0.078 (0.786, 1.090) |
| 2SLS    | NA  | 0.945| 0.200 (0.553, 1.338) |
| PPEL    | 0.04| 0.942| 0.159 (0.631, 1.254) |
|         | 0.06| 0.941| 0.136 (0.675, 1.207) |
|         | 0.08| 0.945| 0.126 (0.698, 1.193) |
|         | 0.12| 0.964| 0.150 (0.669, 1.259) |
|         | 0.16| 0.967| 0.152 (0.669, 1.266) |

NOTE: Our sample size is 56, after removing countries with missing variables from the original sample of 64 countries, so the 2SLS point estimate is 0.945, slightly different from AJR’s 1.00. The line with bold font follows the simulation exercise which sets the constant of the tuning parameter as $0.08$.

Our PPEL estimation the main equation as

$$\log \text{GDP per capita} = 2.048 + 0.945 \times \text{institution} - 0.785 \times \text{latitude}. $$

For the estimation and inference of the key parameter of interest $\beta_\zeta$, we compare the results of PEL, DB-PEL, PPEL and the conventional 2SLS. Its point estimation (PE), STD, and CIs are presented in Table 4. Enjoying the efficiency gain from the extra IVs, the STD of PPEL is 0.126 when we select the tuning parameter $\zeta = \zeta_0(n^{-1}\log p)^{1/2}$ with $\zeta_0 = 0.08$ (the boldface row), as suggested by our simulations. This STD achieves a 37% reduction relative to that of the plain 2SLS with the sole valid IV. Moreover, when we vary the constant $\zeta_0 = 0.08$ in $\zeta$ as 0.04, 0.06, 0.12 and 0.16, PPEL is rather robust over the wide range of tuning parameters.

Our method is particularly important in unifying the IV selection in AJR’s Tables 7 and 8 into a single set of automatically selected IVs. Among the 11 potential IVs, our moment selection criterion (3.9) invalidates all institutional variables. Five IVs survive the testing: the climate variable mean temperature, the geographic variable distance from coast, and three health variables dummy of yellow fever, infant mortality and life expectancy. All the other health and institutional variables are assessed as endogenous and are unsuitable for IVs in this study. The justification for mean temperature and distance from coast is straightforward because humans were unable to interfere with these natural conditions in the era of colonialism. Furthermore, AJR argued for the validity of dummy of yellow fever, though due to concerns of lack of variation they did not employ it as the main IV (AJR’s p.1393, Paragraph 2). Our variable selection result provides supportive evidence to AJR’s heuristics.

8. Conclusion

This article considers a general setting of an economic structural model with many potential moments, some of which may be invalid. These invalid moments must be disciplined in order to estimate the structural parameter consistently. We propose a PEL approach to estimate the parameter of interest while coping with the invalid moments. We show that the PEL estimator is normally distributed asymptotically, and invalid moments can be consistently detected thanks to the oracle property. To overcome the difficulty of estimating the bias in the limiting distribution of the PEL estimator, we further devise the PPEL approach for statistical inference of a low-dimensional object of interest, which is useful for hypothesis testing and confidence region construction. Simulation exercises are carried out to demonstrate excellent finite sample performance of our methods. We revisit an empirical application concerning economic development and shed new insight about its candidate instruments.

Supplementary Materials

The supplementary materials consists of three parts. Part A provides the proofs and technical details about the methods developed in the present article. Part B reports additional simulation results concerning the linear IV model in the main text and an additional dynamic panel data model, respectively. Part C checks the robustness of PEL in the empirical application.

Acknowledgments

The three coauthors contributed to this article equally. We thank the editor, the associate editor, and two anonymous referees for their constructive comments and suggestions.
