(Dated: March 22, 2022)

Numerical simulations on the total mass, the numbers of bonds on the hull, external perimeter, singly connected bonds and gates into large fjords of the Fortuin-Kasteleyn clusters for two-dimensional $q$-state Potts models at criticality are presented. The data are found consistent with the recently derived corrections-to-scaling theory. However, the approach to the asymptotic region is slow, and the present range of the data does not allow a unique identification of the exact correction exponents.

I. INTRODUCTION

$q$-state Potts models have played an important role in condensed matter physics[1]. Here we study geometrical aspects of the critical Potts clusters, in two dimensions. The $q$-state Potts model $[2]$ is defined through the Hamiltonian

$$\mathcal{H} = -K \sum_{\langle i,j \rangle} (\delta_{\sigma_i, \sigma_j} - 1),$$

where $\langle i,j \rangle$ denotes the summation over nearest neighbor sites $i,j$, the spin variable $\sigma_i$ can take any of the values $1,2,\ldots,q$ and $K$ is the thermal coupling with the factor $1/k_BT$ absorbed in it. It is possible to extend $q$ to real values [1], but here we concentrate on the Potts model with integer values of $q$. In particular, we study Potts models with $q = 1,2,3$, and 4, where the thermal phase transition at the critical inverse temperature $K_c = \ln (1 + \sqrt{q})$ [1] is of second order. Below we present simulations at $K = K_c$.

One defines the fractal clusters in the Potts model through the Fortuin-Kasteleyn (FK) [2] cluster decomposition, which states that the model can be mapped onto a general percolation model. The partition function of the Potts model $Z = \text{Tr}_\sigma e^{\mathcal{H}}$ can be expressed in terms of bond variables as $Z = \text{Tr}_{\text{bonds}} p^b (1-p)^n q^{N_c}$, where $b$ is the number of bonds and $n$ is the number of interactions that did not form a bond in a configuration with $N_c$ clusters [2]. Here, $p = 1 - e^{-K}$, and $\text{Tr}_{\text{bonds}}$ means a summation over bonds. Thus, the problem of a thermal lattice model can be mapped to a graph problem. The FK decomposition has been the starting point for efficient cluster algorithms [2] for simulation of spin models.

The Potts model has been shown to exhibit a rich critical behavior, and it has been related to a number of problems in lattice statistics [1]. Although of great theoretical interest in itself, it also has many experimental realizations. The 1-state Potts model is equivalent to a bond percolation problem [1], and the 2-state Potts model is the same as the Ising model [3]. The $q = 3$ Potts model has been shown to describe absorbed monolayers on two-dimensional (2D) lattices [2,3]. Domany et al. [4] suggested that $N_2$ absorbed on krypton-plated graphite should exhibit the same critical behavior as the $q = 4$ Potts model. More references of the experimental realizations can be found in the review article by Wu [1].

Here we study geometrical aspects of the critical Potts clusters in two dimensions. This is in direct analogy with the geometry of percolation clusters, which has been widely studied [10,11,12,13]. Specifically, we measure the fractal dimensions $D_M$, $D_H$, $D_{EP}$, $D_{SC}$, and $D_G$ describing the scaling of the cluster’s mass, hull, external accessible perimeter [12], singly connected bonds [14] and the gates to narrow-gate fjords [12], respectively, with its radius of gyration $R$. As emphasized by Coniglio [13], many of these fractal dimensions have been derived analytically [14]. Some others have been found more recently [12,16]. Although there exists much numerical work on the percolation clusters (i.e. $q = 1$), we are not aware of any detailed numerical study of most of the above mentioned quantities for $q > 1$, and especially when $q$ approaches the critical value $q_c = 4$.

Section [II] describes the numerical methods used in the simulation of the Potts models. Our numerical simulations show that the asymptotic power law dependence of the various masses on $R$ is approached relatively slowly, and therefore the analysis of the data must include correction terms, particularly as $q$ approaches $q_c$. The theory developed to obtain these correction terms [17] is briefly summarized in Section [II]. We compare our numerical data with the exact predictions in Section [IV]. Finally, we present the summary and conclusions in Section [V].

II. SIMULATION

Numerical simulations of spin models have developed from the local spin flip type algorithm [18] to the more advanced cluster algorithms [1,2]. Our simulations were done on a 2D square lattice with both open and periodic
boundary conditions. Clusters of the $q$-state Potts model were generated using the Swendsen-Wang algorithm \cite{4}, which is based on the cluster decomposition by Fortuin and Kasteleyn \cite{3}. The size of the system in our simulations was 4096 spins for all $q$. Figure \ref{fig:clusters} shows sample clusters for different values of $q$.

All simulations were started with a homogeneous initial condition, with all spins initially parallel to each other. First we thermalized the system to allow the model to equilibrate. Thermalization was checked by measuring both the energy per spin $e$, directly from the Potts Hamiltonian, and the magnetization per spin $m$, using the representation of Potts spins in a $q - 1$ dimensional space \cite{1}.

Thermalization of large spin systems takes a very long time. The quantities of interest in this work show a relatively slow approach to the asymptotic values. Thus, extremely large lattices are required for the analysis of the scaling behavior of the cluster subset masses. When performing simulations on lattices of linear size $L = 2^{12} = 4096$, about 20000 Monte Carlo steps (lattice sweeps) are needed to equilibrate the system.

We devised a simple method to overcome the problem with long thermalization times. We started the thermalization with a small lattice of size $L_1$ and thermalized it. We then periodically copied the spin configuration of the small lattice to a lattice with twice as large a size, $L_2 = 2 \times L_1$, and thermalized it. We continued this process until the desired system size was reached. In practice, it is recommended to compare the values of $e$ and $m$ obtained this way with the values obtained from conventional thermalization to be sure that the system is really thermalized. Alternatively, one can continue running the simulation and collect the values of thermodynamical variables as a function of time and check that there is no increasing or decreasing trend in them. The thermalization method described above allows a speed-up by an order of magnitude in thermalization for a Potts spin system of 1024$^2$ spins.

After the spin system was thermalized, we took samples of the cluster configurations after every 20 spin updates (corresponding roughly to the correlation time for the present system sizes) to get uncorrelated samples. Each cluster of the present configuration was taken separately under investigation. However, as a precaution to avoid some of the finite size effects, we collected the data only from those clusters which did not involve spins on the boundary. For the remaining clusters we determined the masses of the cluster subsets. The total mass of the cluster is defined as the number of occupied bonds in the cluster. The number of bonds belonging to the hull, external perimeter and the number of singly connected bonds were counted using directed walkers that walk on the appropriate cluster perimeter \cite{10,13}.

To measure the number of gates to fjords of different gate sizes ($S_G$) a walk was initiated on the EP. The walker starts from the left vacant neighbor of the lower-left site belonging to the cluster and goes around the cluster on the EP always trying to turn to the right. At each site, we look at the neighbors on the left hand side and check whether the sites within a predefined distance $S_B$ belong to the EP or not. If the sites (and bonds) up to the distance $S_B$ are not EP sites and the site at the distance $S_G$ belongs to the EP, the walker is about to enter a fjord with a gate size $S_G$. All fjords with different gate sizes were counted during a single walk around the cluster with an array of boolean variables that indicate whether the walker is within a fjord of given size. If the walker was in a fjord of a gate size $S_G$, fjords with gate size $S_G > S_G$ were not allowed in the statistics. In practice, all measured values of $S_G$ gave similar results, and we report only the results for $S_G = 1$.

As noted by Aizenman et al. \cite{12}, the scaling concerns fjords whose size $L_F$ is comparable to that of the cluster, $R$, and whose gate’s width is much smaller than $L_F$. The reason for this is easy to understand, since small kinks and pits are a natural part of the fractal cluster’s perimeter. Thus, only large enough fjords were included in the statistics. This was taken into account by choosing a suitable parameter $s$, and counting only fjords with $L_F > sR$.

Since any thermalized spin configuration contains clusters of many sizes, we collected the data in multiplicatively increasing bins of the size of the cluster. Each bin contained the clusters of sizes within $[R_i, R_{i+1} = \sqrt{2} R_i]$.

## III. Corrections to Scaling

In our recent publication \cite{17}, we derived theoretically the corrections-to-scaling terms for the various cluster subset masses. The corrections arise from three different sources: (a) using the renormalization group approach, (b) mapping to the coulomb gas, and (c) considering the uncertainty of the correct measure for the linear cluster size, which implies corrections of the order of $1/R$.

The first correction relates to the dilution field $\psi$, which is generated under renormalization even when one starts with the non-diluted case \cite{19}. Solving the renormalization group recursion relations (RGRR)’s for $\psi(\ell)$, where $\ell$ is the scale variable, substituting the solution to the RGRR’s for the field $h_S$ conjugate to the density $\rho_S = M_S/R^d$ and finally calculating the scaling of the density $\rho_S(\ell)$ with the cluster’s linear size $R = \ell^i$ yields the following predictions for the approach of each mass $M_S$ to the asymptotics. Here, $S = M, H, EP, SC$ or $G$.

In the $q = 4$ case, the renormalization group calculation is exact, yielding logarithmic corrections to the scaling of $M_S(R)$:

$$M_S \propto R^{D_S}(\log R + B \log(\log R) + E)^{-c_S/a} \times (1 + O(\log \log R / \log R)), \quad (2)$$

with $D_S = y_S(q = 4)$ and $c_S/a$ as given in Table \ref{tab:corrections} (see below). Note that $B$ is universal, and the non-universal
constant $E$ is the same for all $S$. Equation (2) generalizes the logarithmic corrections of Cardy et al. [19].

We were recently directed to a previous study by Vanderzande and Marko [20], in which they considered corrections to scaling for percolative properties of the $q = 4$ Potts model. They also found logarithmic corrections to scaling in agreement with those presented here.

For $q < 4$, to leading order in $\epsilon' = \sqrt{4-q}$, the same procedure yields

$$M_S \propto R^{D_S}(1 - \hat{\theta}' - \hat{g} R^{-\theta})^{-c_S/a} \approx R^{D_S}(1 + f_S R^{-\theta}),$$

(3)

where $D_S \approx y_S - c_S \epsilon'$ and $\theta \approx 2a \epsilon'$. Note that to the lowest order in $\epsilon'$, the ratios $f_S/f_S'$ are universal, being equal to $c_S/c_S'$. This is similar to analogous ratios for thermodynamic properties in the usual $\epsilon$-expansion [21]. This universality should hold to all orders in $\epsilon'$. Expanding the exact $D_S$ (Table I) in $\epsilon'$ yields $c_S$. Using also $a = 1/\pi$ [17, 19] yields our predictions for $c_S/a$ (given in Table I), to be used in the fitting procedure.

The second source of corrections involves new contributions to the relevant pair correlation functions in the Coulomb gas representations. den Nijs [22] derived such corrections to the order parameter correlation function. Since correlation exponents $x$ are related to the fractal dimension via $D = d - x$, the correction exponents can be related to the corresponding correction terms for the scaling of the mass $M_M$, yielding the leading correction

$$\theta' = 4/g,$$

(4)

where $g$ is the ($q$-dependent) Coulomb Gas coupling constant (see Table I).

Using a similar approach we found in the case of the hull and the singly connected bonds that the leading correction exponent is given by

$$\theta'' = 2/g.$$

(5)

We argued that this correction would also hold for the external perimeter [17].

The last source of corrections involves ‘analytic’ terms, coming e. g. from linear cuts with dimensions $(D_S - 1)$, [24] or from replacing $R$ by $(R + A)$, since there are many possible candidates for the correct linear measure of the cluster. These would imply corrections of relative size $1/R$.

IV. RESULTS

We now present the numerical data from large scale Monte Carlo simulations of the Potts models. Our aim is to confirm the exact predictions of the fractal dimensions $D_S$ in the cases where they are available and to give numerical estimates for the exponents that have not yet been calculated exactly. In addition, we want to numerically confirm the corrections-to-scaling theory presented in the previous section.

We obtain good agreement with the theoretically predicted values for most of the fractal dimensions $D_S$. The worst agreement is found for the exponent of the external perimeter $D_{EP}$ for $q > 2$ Potts models. The reasons for this will be discussed below. However, fixing the correction terms and performing fits only to the amplitudes and to the fractal dimensions $D_S$ in the logarithmic derivatives of Eqs. (4) and (5), yielded estimates for the subset fractal dimensions that agree to the precision of 0.05 or better with the theoretical predictions of Table I.

We are not able to give a quantitative numerical proof of the values predicted for the correction terms. Qualitatively, our numerically evaluated functions $M_S(R)$ display a complex corrections-to-scaling behavior that requires more than one correction term. The theoretical predictions can be fitted reasonably well to the data keeping the important quantities such as $\theta, \theta'$ (or $\theta''$) and $c_S/a$ fixed while leaving the amplitudes of individual correction terms free.

We start this section by studying the fractal geometry of clusters in the site percolation model, which is computationally easier to simulate. The reasons behind the difficulties in the comparison of the numerical data with the analytical predictions are discussed. We then proceed to present our numerical data on the Potts clusters. In all the figures of this Section, whenever the error bars are not shown they are smaller than the size of the symbols.

A. Site Percolation Clusters

For $q = 1$ we simulated site percolation on a square lattice of size $24576^2$, using the Newman-Ziff cluster labeling [25] which is an improved version of the Hoshen-Kopelman algorithm [26]. Thus the linear size was 6 times larger than in the simulation of Potts clusters with $q > 1$.

To get a feeling of what kind of problems are present in the fitting procedure when the theoretically predicted correction terms of Eqs. (4) and (5) are fitted to the numerical data on the cluster subset masses $M_S(R)$, let us consider as an example the scaling of the number of singly connected bonds. Figure 2 illustrates the scaling of $M_{SC}(R)$ with the cluster size $R$ on a double logarithmic scale. The solid line in the main figure indicates the predicted slope. The fit to the data yields an estimate for the asymptotic fractal dimension $D_S$ which is less than 0.01 off the exactly known value $D_{SC} = 3/4$.

Although the asymptotic scaling regime $M_{SC}(R) \propto R^{D_{SC}}$ can be seen here, there are difficulties in the extraction of the correction terms of Eq. (4). The smallest value of $R$ included in the linear fit to the data on log – log scale in Fig. 2 corresponds to the regime where the influence of the correction terms are about to vanish, thus justifying fitting without any correction terms. The saturation to the asymptotics can be seen more clearly in the inset of Fig. 2 where data are scaled with the predicted asymptotic behavior $M_{SC}(R)/R^{D_{SC}}$. The inset
shows that at about $R \approx 300$ the correction terms can be neglected in this case. However, at the same point the statistics becomes so noisy, making a precise estimation of the correction terms difficult. An additional difficulty arises from the fact that the finite size of the lattice is not taken into account in any way in the finite size scaling form of Eq. (6). Due to the finite system sizes, statistics of the large cluster is biased in such a way that only the compact clusters fit in the lattice without touching the boundaries. The extended clusters having for example more EP sites than compact clusters with the same radius of gyration $R$, are absent. This bias cannot be taken into account by any known correction terms. We tried to extrapolate the data from different system sizes to obtain an asymptotic curve for an infinitely large system, but the statistics is far from sufficient for such a procedure.

B. Potts Clusters

In the case of Potts clusters, system sizes that can be used in the simulations are much smaller than those in the site percolation case, since in addition to the spin variables, also bonds must be stored in the computer memory. This causes the finite size effects to be even more pronounced than those present in the site percolation model simulations. In addition, the correction exponents in the $1 < q < 4$ Potts models are smaller than those in the $q = 1$ case. Also, the logarithmic corrections present in the 4-state Potts model are weaker than any of the power law corrections in $q < 4$ models. Thus, the influence of the corrections-to-scaling terms extends to much larger values of $R$.

The data analysis was done by fitting the theoretical predictions of Sect. III to the data. The nonlinear fitting was done using the Levenberg-Marquardt method [26]. The measure for the quality of fits is $\chi^2$. Values of $\chi^2$ close to one indicate a good fit. We determined the error bars of the fractal dimensions by fixing $D_S$ to a range of values around the theoretically predicted one, and performing a fit to the amplitudes for each such value. The error bar on $D_S$ was fixed as the range within which $\chi^2$ remained smaller than 2. One can perform the fit directly to $M_S(R)$, or to the effective fractal dimensions $D^{\text{eff}}_S(R)$ (which is the logarithmic derivative of $M_S(R)$ [11]).

We found that for $q < 4$, fitting directly to the mass worked out better. If one wants to fit to the measured data directly, it is recommended to divide the measured data on the cluster subset masses by the exactly known asymptotic behavior to avoid problems with numerical accuracy. Thus, for $q < 4$, the fits are done to the form

$$M_S/R^{D_S} = E_S(1 + f_SR^{-\theta} + f_{\theta}'R^{-\theta'} + gs/R),$$

(6)

where $E_S, f_S, f_{\theta}', g_S, \theta$ and $\theta'$ are the fitting parameters, and the fractal dimensions $D_S$ are kept fixed.

In the $q = 4$ case, on the other hand, we found the fitting to the effective exponent $D^{\text{eff}}_S$ better, and the fits were thus done to

$$D^{\text{eff}}_S = d \log M_S/d \log R$$

$$\approx D_S - \frac{(cS/a)(B + C + \log R)}{(C + \log R)(E + \log R + B \log(C + \log R))} + Z/\log R.$$

(7)

Note that we have replaced the $\log \log$ term in Eq. (6) by the more general $\log(C + \log R)$. Also, the logarithmic derivative of the higher order term on the RHS of Eq. (6) was approximated by a simpler form $1/\log R$. In the fitting procedure, the possibility of having many candidates for the correct linear measure of the cluster size was taken into account by allowing $R$ to adjust to $R + A$ (see Sect. III).

Below, the results of our numerics are summarized for the various subsets. We do not go into the details of numerical estimates for the various amplitudes in the nonlinear fits, since due to the relatively small range of the data and many fitting parameters the estimated error bars are large, and allow no comparison with, for example, the predicted amplitude ratios. Also, precise estimation of the correction exponents $\theta, \theta'$ (or $\theta''$) as well as the parameters $cS/a$ is impossible with the presently available range of data. Instead, we keep the correction exponents (or parameters) fixed and try to extrapolate the fractal dimensions $D_S$, and to demonstrate that the predicted forms of scaling in Eqs. (7) and (6) are consistent with our numerical data. Specifically, in all the fits for $1 \leq q < 4$, $\theta$ and $\theta'$ (or $\theta''$) of Eq. (6) were kept fixed (at the predicted values), while the amplitudes of each correction term were allowed to adjust. In the $q = 4$ case, only $cS/a$ was fixed in Eq. (7).

The logarithmic corrections are most important for the singly connected bonds at $q = 4$, where theory predicts that $D_{SC} = 0$ (see Table I). Indeed, the solid line in Fig. 8 shows that a fit to Eq. (7) is consistent with this theoretical prediction. In contrast, a fit with a single power law correction term $\theta = 1/2$ (dashed line in Fig. 8) extrapolates to a wrong value near $D_{SC} = 0.21!$

1. Mass

Fig. 9 shows an example of the fit to the curve $M_M(q = 3)/R^{D_M}$. In the fitting procedure, $D_M, \theta$ and $\theta'$ were kept fixed while $E_M, f_M, f_{\theta}'M$ and $g_M$ were allowed to fit. The value $\chi^2 = 1.17$ indicates that Eq. (6) gives a good representation of the data. Our numerical estimates for the fractal dimensions $D_M(q)$, determined as the range of values for which one has $\chi^2 < 2$, are 1.90 $\pm$ 0.01, 1.87 $\pm$ 0.01, 1.85 $\pm$ 0.02 and 2.05 $\pm$ 0.15 for $q = 1, 2, 3, 4$, respectively. These are in good agreement with the theoretical predictions.
2. Hull

Figure shows a fit to the number of the bonds belonging to the hull in the \( q = 4 \) Potts model. In this particular fit, \( D_H \) and \( c_H/a \) were kept fixed while \( B, C, Z \) and \( A \) were free to adjust. The value of \( \chi^2 = 1.11 \) indicates that Eq. (7) fits the data well. Our numerical estimates for the fractal dimensions \( D_H(q) \) are \( 1.75 \pm 0.01, 1.66 \pm 0.01, 1.59 \pm 0.03 \) and \( 1.50 \pm 0.01 \), for \( q = 1, 2, 3, 4 \), respectively. Agreement with the theoretical predictions is excellent as can be seen by comparison with the values in Table I.

3. External Perimeter

Figure shows an example of the fit to the external perimeter data in the \( q = 2 \) Potts model. The fractal dimension \( D_{	ext{EP}} \) and the correction exponents \( \theta \) and \( \theta'' \) were kept fixed at the predicted values while \( E_{	ext{EP}}, f_{	ext{EP}}, f'_{	ext{EP}} \) and \( g_{	ext{EP}} \) were free to adjust yielding \( \chi^2 = 1.77 \), implying a reasonably good agreement with Eq. (9). Again, in the fits for \( q < 4 \), \( \theta \) and \( \theta'' \) of Eq. (6) were free to adjust and in the \( q = 4 \) case, \( c_{	ext{EP}}/a \) was fixed. The numerical estimates \( 1.33 \pm 0.05, 1.36 \pm 0.02, 1.40 \pm 0.02 \) and \( 1.48 \pm 0.02 \) for \( q = 1, 2, 3, 4 \), respectively, agree with the exact predictions.

4. Singly connected bonds

In Fig. we show the number of singly connected bonds \( M_{	ext{SC}}(R)/R^{D_{	ext{SC}}} \) against the cluster size \( R \) in the \( q = 2 \) Potts model. The fractal dimension \( D_{	ext{SC}} \) and the correction exponents \( \theta \) and \( \theta'' \) were kept fixed to the predicted values while \( E_{	ext{SC}}, f_{	ext{SC}}, f'_{	ext{SC}} \) and \( g_{	ext{SC}} \) were allowed to fit. The value \( \chi^2 = 1.21 \) implies good agreement with Eq. (8). The numerical estimates for the fractal dimensions are \( 0.75 \pm 0.02, 0.55 \pm 0.03, 0.35 \pm 0.07 \), for \( q = 1, 2, 3, 4 \), respectively. All the estimates for the fractal dimensions \( D_{	ext{SC}} \) are in good agreement with the theoretical predictions. However, the large value of \( \chi^2 \approx 3 \) in the \( q = 4 \) case indicates some discrepancy between Eq. (7) and the data.

5. Gates to Fjords

Figure shows our numerical data for the number of gates to narrow-gate fjords. The figure shows fits to the data along with the estimates for the fractal dimensions \( D_G \). Our estimate \( D_G(q = 1) = -0.9 \pm 0.05 \) agrees with the exact prediction \( D_G = -11/12 \approx -0.92 \). Here, only a linear fit to the data on the double logarithmic scale was considered, since the scaling regime for the presently available cluster sizes is rather narrow. The parameter \( s \) governing the minimal ratio of the fjord size to the cluster size that we used was in the range \( 0.1 \leq s \leq 0.2 \). The actual choice for the value of \( s \) does not affect the scaling law, but it merely determines the range where the power law behavior \( M_G \sim R^{D_G} \) starts (decreasing \( s \) shifts the maximum of the curves \( M_G(R) \) to the left). Our numerical estimates for \( |D_G(q)| \) decrease with increasing \( q \). Our estimates for \( D_G(q) \) are \( -0.90 \pm 0.05, -0.71 \pm 0.05, -0.63 \pm 0.05 \) and \( -0.59 \pm 0.05 \) for \( q = 1, 2, 3, 4 \), respectively. Our numerical estimates together with the theoretical predictions for all fractal dimensions \( D_S \) are summarized in Table II.

VI. CONCLUSIONS

The present paper examined the fractal geometry of the Potts clusters at the critical temperature. The aim was to find numerical evidence on the exactly derived subset fractal dimensions \( D_S \) and to give estimates on the dimensions for which there is no exact prediction. We gave the first numerical estimate of the negative fractal dimensions \( D_G \), describing the scaling of the gates to fjords.

Analysis of our numerical data revealed a slow and complex approach to the asymptotic behavior. If this is neglected in data analysis, wrong numerical estimates for the dimensions \( D_S \) follow. Using the corrections-to-scaling terms derived in our earlier publication, in the fitting procedure, excellent agreement with most of the exact dimensions and data was found. The present quality and range of data does not allow a unique quantitative confirmation of the exact correction parameters.

To summarize, in the comparison between theory and numerics, extreme caution is needed in the extraction of the fractal dimensions \( D_S \) from the numerical data. The corrections-to-scaling theory presented already implies that the finite size effects arising from the finite cluster size are strong. In addition, effects coming from the finite lattice size lead to an uncontrollable bias that is very difficult to handle.

| $G$ | $-0.90(5)$ $^{-1/2}$ | $-0.71(5)$ $^{-1/2}$ | $-0.63(5)$ $^{-1/2}$ | $-0.59(5)$ $^{-1/2}$ |

TABLE II: Comparison of the numerical estimates (n) for the subset fractal dimensions $D_S$ with the exact predictions (e) where available. Uncertainties of the last decimal(s) for each $D_S$ are given in parenthesis.
FIG. 1: Computer generated Potts clusters for (a) $q = 1$, (b) $q = 2$, (c) $q = 3$ and (d) $q = 4$ state Potts models. Colors indicate different subsets: SC bonds are shown in red, H bonds are shown in yellow and the rest of the bonds contributing to M are shown in blue. The EP bonds are colored green and the gates to fjords are marked by black circles, while the fjord is shown with a black line. For all the clusters, the total masses $M_M$ are in the range $14400 – 17600$. Note the decrease of $D_H$ with $q$. 
FIG. 2: Site percolation model. The number of the singly connected bonds $M_{SC}(R)$ vs. the cluster linear size $R$. The predicted slope $D_{SC} = 3/4$ is indicated by the solid line. The inset shows the scaled mass $M_{SC}(R)/R^{D_{SC}}$. Note the saturation to the asymptotic scaling at $R \approx 300$. 
FIG. 3: Example of different fits in the $q = 4$ Potts model to $M_{SC}(R)$. The dashed line shows a fit with a single power law correction ($\theta = 1/2$) and the solid line shows the fit to the logarithmic form of Eq. (7). Note the difference in the extrapolation to the $R \rightarrow \infty$ where the fits give $D_{SC} = 0.21 \pm 0.01$ with a single power law correction term whereas $D_{SC} = 0.03 \pm 0.08$ with the logarithmic form.
FIG. 4: Total mass of the cluster mass $M_M$ in the 3-state Potts model. Solid line is the nonlinear fit to the data. For this particular fit $\chi^2 = 1.17$. 
FIG. 5: Effective exponent $D_{eff}^H(R)$ against $1/R$ in the $q = 4$ Potts model. For the fit indicated by the solid line we find $\chi^2 = 1.11$. 
FIG. 6: Number of the external perimeter bonds, $M_{EP}$ versus $1/R$ in the $q = 2$ Potts model. Solid line indicates the fit to the data ($\chi^2 = 1.77$).
FIG. 7: Number of the singly connected bonds $M_{SC}$ against $1/R$ in the $q = 2$ Potts model. Solid line is the nonlinear fit for which $\chi^2 = 1.21$. 
FIG. 8: Data for $M_G(R)$, the number of gates to fjords on log-log scale. Different values of $q$ are represented by the symbols shown in the legends. Straight lines indicate the fits to the data; slopes give the exponents $D_G$. 

$\log(R) = -2 \quad -1.5 \quad -1 \quad -0.5 \quad 0$

$log[M_G(R)]$

$q=1; D_G = -0.90$
$q=2; D_G = -0.71$
$q=3; D_G = -0.63$
$q=4; D_G = -0.59$
