Abstract

Collective effects, such as waves and instabilities, are integral to our understanding of most plasma phenomena. We have been able to study these in ultracold neutral plasmas by shaping the initial density distribution through spatial modulation of the ionizing laser intensity. We describe a relay imaging system for the photoionization beam that allows us to create higher resolution features and its application to extend the observation of ion acoustic waves to shorter wavelengths. We also describe the formation of sculpted density profiles to create fast expansion of plasma into vacuum and streaming plasmas.

1. Introduction

Collective modes are central to our understanding of plasma dynamics and transport properties [1, 2]. They often lead to instabilities [3] that can dominate plasma dynamics and create significant complications for practical applications such as magnetic confinement fusion. In principle, and for most regimes of plasma density and temperature, these phenomena are well described within classic theoretical frameworks such as continuum fluid or kinetic descriptions, but the possible complexity in plasmas is continually leading to the observation of interesting new phenomena. In addition, at relatively high densities and/or low temperatures, when plasmas become strongly coupled, or non-ideal [4], plasma dynamics becomes hard to describe theoretically or simulate numerically, so new experiments probing this regime are of great fundamental interest and important for understanding the behaviour of matter under extreme conditions of energy and density [5].

Recent advances in plasma creation have allowed for the excitation of ion collective modes in ultracold neutral plasmas (UCNPs) [6]. UCNPs [7, 8] are formed by photoionizing laser cooled atoms near the ionization threshold, and they access an exotic regime of plasma physics in which electron and ion temperatures are orders of magnitude colder than those in traditional neutral plasmas. These plasmas have unique properties arising from their ultracold temperature, small size and expansion dynamics. They also display correlated particle dynamics [9–14] that reflect strong coupling [2] of the constituents, which allows them to probe a regime of nature in which correlated, many-body interactions are dominant.

In strongly coupled systems, the Coulomb interaction energy exceeds the thermal energy, as characterized by a Coulomb coupling parameter, \( \Gamma \geq 1 \), where

\[
\Gamma = \frac{e^2}{4\pi \varepsilon_0 a k_B T}.
\]

Here, \( T \) is the temperature and \( a \) is the Wigner–Seitz radius, \( a = \left[ 3/(4\pi n) \right]^{1/3} \) for the density \( n \). Because of the low temperature in UCNPs, ions equilibrate with \( 2 < \Gamma_i < 5 \) [10, 12]. It is possible to set initial conditions for a large electron \( \Gamma_e \), but heating processes involving many different collisional effects will lower the coupling to \( \Gamma_e \leq 0.2 \) [15–19] within a few microseconds. For \( \Gamma > 1 \), particle correlation effects become important.

A wide range of phenomena has been studied in UCNPs, such as expansion of the plasma into surrounding vacuum with [20] and without [18, 21, 22] an applied magnetic field, adiabatic cooling of electrons during expansion [19, 20], three-body recombination at ultracold temperatures [19, 23, 24], spontaneous evolution of a frozen Rydberg gas into an ultracold plasma [25], equilibration of ions after plasma creation [11, 26] and disorder-induced heating of electrons [16, 17] and ions [9, 11, 14, 26] and kinetic energy oscillations [11, 26, 27] due to effects of strong coupling. Langmuir oscillations have been resonantly excited and used as a probe of...
plasma density [28, 29], and an $\mathbf{E} \times \mathbf{B}$ electron drift instability was also observed [30].

Recently, Castro et al [6] used a new technique involving spatially masking the photoionization-laser intensity to shape the initial density distribution of UCNPs and excite long-wavelength ion acoustic waves (IAWs). The excitation wavelength was as short as $\lambda \approx 500 \mu\text{m}$ with the limit set by diffraction effects. Shorter wavelength excitations would access more interesting physics, such as the transition from a sound wave to a dispersionless ion plasma oscillation when the wavelength becomes on the order of the Debye screening length, $\lambda_D = (\varepsilon_0 k_B T_e / n_e e^2)^{1/2}$, where $T_e$ and $n_e$ are the electron temperature and density respectively. Furthermore, corrections to the IAW dispersion relation due to strong coupling of ions are predicted for $\lambda \lesssim a$ [31–37] and sharp features in the ion density profile should also lead to large ion accelerations that may excite shock waves [7, 15] and solitons [38]. In this paper we present improvements to the ionization system that decrease the observable excitation wavelength to $\sim 100 \mu\text{m}$, approaching the Debye length under accessible UCNP conditions and only ten times the Wigner–Seitz radius.

2. Experimental setup

Strontium UNCPs are created in a magneto-optical trap (MOT) containing $\sim 300$ M laser-cooled $^{88}$Sr atoms by photoionizing approximately half of the atoms near the ionization threshold with a pulsed narrowband laser [7]. The density distribution of the atoms is a spherical Gaussian, $\propto \exp(-r^2/2\sigma^2)$, with characteristic radius $\sigma \sim 1–2$ mm, and if the ionization beam intensity profile is uniform, the plasma has a similar form. The electrons have a tunable temperature, $(\frac{3}{2} E_e / k_B \sim 1–100 \text{ K})$, determined by the energy difference $(E_e)$ between the ionizing photon and the ionization potential. The ions, with their relatively large mass, inherit the temperature of the laser-cooled atoms ($\sim 10$ mK).

Two-photon ionization is realized with one photon from a pulse amplified beam of light from the cooling laser, driving the Sr $^1S_0$–$^1P_1$ transition at 461 nm, and a second photon from a pulsed dye laser, at 412 nm, which promotes the electron to the continuum. We use a mask on the second ionizing beam in order to spatially modulate the laser intensity. This simple technique allows one to spatially manipulate the ionization fraction, in turn controlling the initial density distribution of the UCNP. For instance, masking half of the beam with a straight edge produces a single Gaussian hemisphere of plasma. Further flexibility is provided by the option of reflecting the ionizing beam through the chamber a second time to increase the ionization fraction, and by masking only the second pass of the 412 nm ionizing beam we can create smaller amplitude perturbations. For example, a 100% contrast square wave mask was used in this fashion in previous studies to excite low-amplitude IAWs with user-selected wavelength [6]. Although highly versatile, this straightforward technique is limited in terms of achievable feature size due to laser diffraction over the distance from the mask to the plasma. To overcome this limitation we have implemented a relay lens system to image the mask onto the plasma with much higher resolution.

Our design consists of a matched, positive focal length lens pair (Thorlabs AC508-200-A $f = 200$ mm achromatic doublets) in a 1:1 conjugate ratio. To achieve maximum performance, many factors, such as lens aberrations, alignment and aperture, must be balanced against experimental design limitations, but this configuration was predicted with Lambda Research’s OSLO optical design software to produce a contrast transfer function (CTF) of 50% for a 50 cyc mm$^{-1}$ pattern. The lenses are held in place with a custom lens tube adapter that can be securely attached to the vacuum chamber. This direct mounting method ensures correct and reproducible mask-lens-plasma alignment (coaxial with ionizing beam and distance $f$ from the plasma). Transmission masks are mounted a distance $f$ back in a $\theta_z$ rotation mount atop an $x_z$ translation stage (laser propagation $\hat{k}/|\hat{k}| = \hat{z}$). Rotational alignment ensures that ionized edges are aligned vertically with the plasma imaging system’s line of sight, $x$ alignment allows centring of a pattern transversely on the plasma, while the micrometer $z$ adjustment allows fine positioning of the mask image so that the atoms are centred within the depth of field.

3. Improved resolution

We measured the CTF of the ionization relay system by imaging a 1951 USAF resolution target onto a CCD camera. The CTF is calculated from the normalized signal ($S$) as CTF$(\nu) = (S_{\text{max}}(\nu) - S_{\text{min}}(\nu))/(S_{\text{max}}(\nu) + S_{\text{min}}(\nu))$, where $\nu$ is the spatial frequency of the square wave pattern. The system exceeded design goals, with a CTF of $\sim 100\%$ at 20 cyc mm$^{-1}$ over the typical depth of field of the plasma $\pm 2$ mm and maximum focal plane resolution of CTF $\sim 100\%$ at $>80$ cyc mm$^{-1}$. Note, this later measurement was limited by CCD pixel size.

In situ diagnostics of the ionizing relay system was accomplished with fluorescence imaging of the Sr$^+$ ions, on the principal transition, $^2S_{1/2}$–$^2P_{1/2}$ at 422 nm [39] (figure 1).
A sheet of light, with a beam waist of 625 μm, propagating perpendicular to the imaging system line of sight and 106° away from the 412 nm ionizing beam, is used to excite fluorescence. Relative plasma density in the illuminated region is measured directly by scanning the imaging laser over the doppler broadened resonance of the entire plasma cloud and summing the captured fluorescence in post-analysis. Absolute calibration of density is accomplished with complimentary absorption imaging [10]. From the 2D images we create 1D slices by cropping a narrow strip perpendicular to the density features and integrating along the narrow dimension (figures 2(a) and (b)). For these measurements, a single pass of the ionizing beam through the chamber is used, which should lead to 100% density contrast for well-resolved patterns. Using analysis tools and square wave masks of various wavelengths we measured contrast of the imaged plasma density, which represents a CTF of the entire ionizing/imaging system. Figure 2(b) shows one such measurement where we achieve our highest resolution of CTF = 13.5% at 10 cyc mm⁻¹.

This resolution limit is significantly worse than what was measured for the photoionization relay during bench testing. Effects of plasma dynamics and misalignment of the planes of constant density with the line of sight of the imaging system cannot explain the discrepancy. We suspect that the imaging system is currently limiting our resolution and the plasma density features have higher contrast. Improvements to the imaging system are now underway.

4. Experiments with sculpted UCNPs

The observed resolution represents a five-fold improvement over the results presented in [6], and we can now study plasmas with density modulations with spatial frequency as high as 10 cyc mm⁻¹. To isolate the density modulations, density profiles such as the one shown in figure 2(b) are fit to a Gaussian profile and then divided by the fitted Gaussian. With time-resolved imaging, we observed the evolution of the ion density modulation (figure 3(a)), which can be described in terms of IAWs similar to [6]. IAWs are longitudinal density
modulations with slow enough ion dynamics for electrons to remain isothermal. In an infinite homogeneous medium, IAWs have the following dispersion relation for the frequency $\omega$ and wave vector $k = 2\pi/\lambda$:

$$\left(\frac{\omega}{k}\right)^2 = \frac{k_B T_e/M}{1 + k^2 \lambda_D^2},$$

(2)

where $M$ is the ion mass.

For the short-wavelength IAWs that are now accessible, the higher frequency allows a simpler analysis than used previously [6]. The oscillation period is small compared to the plasma expansion timescale; therefore, the electron temperature and IAW wavelength, which affect the oscillation frequency, do not change significantly during the wave period. This permits a simple description of the density perturbation as a constant wavelength, constant frequency, standing IAW, i.e.

$$\delta n = A_0 e^{-\gamma t} \cos(kx) \cos(\omega t),$$

where $A_0$ is the initial amplitude, and $\gamma$ is an exponential decay rate. A fit of this model to data shown in figure 3(a) yields a radial oscillation frequency of $\omega = 3.6(1) \times 10^6$ s$^{-1}$ and a decay rate $\gamma = 9(1) \times 10^5$ s$^{-1}$.

Figure 3(b) shows the comparison of measurements and theory for the dispersion relation. At higher resolution, the wavevector is in the transition regime from linear, acoustic behaviour to the limiting case of a dispersionless ion plasma oscillation with $\omega_{pi} = \sqrt{n e^2/M \epsilon_0}$ for large $k$. With higher electron temperature, which is easily accessible, we can push further into this regime. The measurement, however, does not show the expected rollover. This could be due to the initial density modulation being much larger than in previous studies [6] because equation (2) is only valid when the excitation is a small perturbation to the density distribution.

The observation of fast damping of the oscillation is also an interesting observation. The damping is much stronger than that observed at longer wavelengths [6], which may indicate the influence of Landau damping since this effect becomes large as the wavelength decreases [40]. Variation of frequency across the sample due to variation of density and $\lambda_D$ may also contribute to the decreasing amplitude. With our increased resolution, we can now study damping in detail.

Beyond IAW dispersion and damping, we can also study a variety of situations in which plasmas are strongly accelerated into the vacuum or into another plasma. Large plasma density
gradients, accessible with high resolution photoionization, produce large plasma accelerations and velocities, enabling the study of nonlinear effects such as shock formation and solitons [3, 7, 15, 38]. The importance of the density gradient can be seen from a hydrodynamic description using the coupled ion–electron momentum balance equations at early times when ion velocities are small [28]. Acceleration of the ions (\(a_0\)) is provided by the electron pressure (\(P_e\)) according to \(\frac{Mn_0}{\sigma_0} \approx -\nabla P_e \approx -\nabla [nkBT_e(0)]\). \(T_e(0)\) is expected to be close to uniform [15], leading to acceleration that varies as \(\nabla n\). For an unperturbed UCNP, the density profile is a spherical Gaussian with \(|-\nabla n| \approx n/\sigma_0\), giving the characteristic radial acceleration on a timescale of about 10 \(\mu s\) that has been studied extensively in the context of self-similar plasma expansion [7]. However, when sharp features with length scale \(l \ll \sigma_0\) are imprinted on the plasma density, the local gradient and resulting plasma acceleration and velocity can be much larger.

A simple configuration is the total attenuation of half of the ionizing beam. This creates a single, hard-edged, hemisphere with rapid expansion perpendicular to the edge. Figure 4 shows this configuration and a clear picture of the maximum density gradient currently observable. Further studies will allow us to characterize this effect and possibly observe strongly supersonic velocities that may produce shock waves.

Another interesting configuration utilizes a single opaque wire for the transmission mask, thus creating two plasma hemispheres with an adjustable gap in between (see figure 5). In this geometry, ions accelerate into the central void, where they can interact. Preliminary studies have shown a strong dependence on experimental parameters (density, gradient and electron temperature) of the ability for streaming plasmas to penetrate each other. Additional studies will probe subsonic and supersonic plasma velocities and look for effects of strong coupling.

5. Conclusion

A new relay lens system on the photoionization laser beam has resulted in at least a five-fold improvement in ionizing resolution compared to previous studies of sculpted UCNPs [6], allowing access to many interesting plasma experiments. We have measured shorter wavelength IAWs with very fast damping and observed ions that are accelerated strongly by a sharp plasma gradient. To ensure that imaging system performance does not limit the observable resolution a transportable imaging system is being constructed and bench tested. Considering the experimentally accessible NA, single-pixel (~13 \(\mu m\)) features should be imaged with 100% fidelity.
