(Dated: July 15, 2020)

We reveal the universal effect of gauge fields on the existence, evolution, and stability of solitons in the spinor multidimensional nonlinear Schrödinger equation. Focusing on the two-dimensional case, we show that when gauge field can be split in a pure gauge and a non-pure gauge generating effective potential, the roles of these components in soliton dynamics are different: the localization characteristics of emerging states are determined by the curvature, while pure gauge affects the stability of the modes. Respectively the solutions can be exactly represented as the envelopes independent of the pure gauge, modulating stationary carrier-mode states, which are independent of the curvature. Our central finding is that nonzero curvature can lead to the existence of unusual modes, in particular, enabling stable localized self-trapped fundamental and vortex-carrying states in media with constant repulsive interactions without additional external confining potentials and even in the expulsive external traps.

Gauge fields are ubiquitous in physical theories ranging from classical electromagnetism \textsuperscript{1}, theories of molecular \textsuperscript{2}, spinor \textsuperscript{3}, and many-body \textsuperscript{4} systems, to particle physics \textsuperscript{5} and gravity \textsuperscript{6}. Gauge fields can be artificially created in atomic systems \textsuperscript{7}, a spin-orbit coupled (SOC) Bose-Einstein condensate (BEC) \textsuperscript{8} being a celebrated example, and in photonics \textsuperscript{9}. Since nonlinearity is naturally present in these systems, the effect of the gauge fields on dynamics of nonlinear waves in them has become a subject of growing interest. New types of spatially localized nonlinear waves - solitons - were introduced in SOC BECs. In one-dimensional (1D) settings solitons with various symmetries imposed by a constant \textsuperscript{10}, spatially dependent \textsuperscript{11–13}, and nonlinear gauge fields \textsuperscript{14}, were proposed in pseudospin-1/2 BECs, as well as in SOC-BECs with integer pseudospin \textsuperscript{15}. It was established \textsuperscript{12–13} that inhomogeneous gauge fields may be described by an integrable extension of the Manakov model \textsuperscript{16}, i.e., by coupled nonlinear Schrödinger (NLS) equations with SU(2)-symmetric nonlinearity.

Gauge fields in 2D nonlinear dynamics may have remarkable stabilizing effect. Already in \textsuperscript{17} it was noticed that combination of a rotating trap with external parabolic potential, viewed as a gauge potential, sustains stable solitons of 2D NLS equation. A possibility of confinement by a gauge field in a spinor BEC in the quasirelativistic limit was mentioned in \textsuperscript{18}. Solitons and half-vortices in SOC BECs were reported in the presence of Zeeman lattices \textsuperscript{19, 20}, in free space \textsuperscript{21, 22}, and in dipolar SOC BECs \textsuperscript{23}. Stable 2D solitons were also found in optical media with dispersive coupling mimicking SOC \textsuperscript{24}. Thus, it was shown that SOC by itself can stabilize 2D solitons in media with attractive interactions. Moreover, stable self-trapped modes have been found numerically in SOC-BECs with self- and cross-interactions of different signs \textsuperscript{25}. At the same time, spatially localized 2D BEC solitons with all repulsive interactions under the action of gauge fields have been studied only in the presence of either external traps \textsuperscript{26, 27} or lattices \textsuperscript{10}. There exist also theoretical predictions of metastable solitons in 3D SO-BECs sustained by 3D SOC \textsuperscript{28}, as well as solitons sustained by 2D SOC in the presence of a Zeeman splitting \textsuperscript{21}.

In this Letter we show that pure gauge and non-pure gauge components of the field have profoundly different effects on nonlinear modes. A spatially localized solution of SU(2)-symmetric NLS equations allows for the (exact) representation [see (2) below] in a form of a carrier state (determined by the pure gauge) which is modulated by the envelope evolving in an effective potential induced by the non-pure gauge. Thus, the latter affects the very existence of solitons. In contrast, the pure gauge does not have impact on the existence of nonlinear modes. However, by changing the structure of the carrier states, i.e., the internal structure of solitons, it does affect the soliton stability. Breaking SU(2) symmetry by nonlinearity reveals stabilizing properties of the field that is pure gauge in the SU(2) limit. Exploring the 2D case, we illustrate confining and stabilizing (or destabilizing) effects of a gauge field on solitons in the repulsive medium without confining linear potentials, and even in the presence of expulsive traps. Remarkably, even vortex solitons can be stabilized by gauge fields.

The model and gauge transformation— The phenomena described below are governed by the two-component NLS equation:

\begin{equation}
\psi_t = \frac{i}{2} \left[ -i \nabla + A(x) \right]^2 \psi + V_0(x) \psi + G(\psi^\dagger, \psi) \psi
\end{equation}

for a spinor \( \psi(x,t) = (\psi_1, \psi_2)^T \) in a \( d \)-dimensional space \( x \in \mathbb{R}^d \). In Eq. (1), \( A(x) = (A_1, ..., A_d) \) is the...
vector gauge field, whose entries \( A_{ij}(x) \) are Hermitian 2 \( \times \) 2 matrices, the matrix \( G(\Psi^\dagger, \Psi) \) describes the nonlinearity, and \( V_0(x) \) is the external potential. The gauge field determines the curvature \( F_{mn}(A) = \partial_m A_n - \partial_n A_m - i[A_m, A_n] \), where \( \partial_n = \partial/\partial x_n \). One can define an effective "magnetic" field \( \tilde{B} \) as \( B = \varepsilon_{mn} F_{mn}(A) \) and \( B_1 = \varepsilon_{mn} F_{mn}(A) \), in 2D and 3D cases, respectively, where \( \varepsilon \) is the Levi-Civita symbol (here the sum over repeated indexes is computed).

In the linear case \( (G = 0) \) a gauge field generating zero curvature (alias, pure gauge) can be gauged out provided that space domain is simply connected. The possibility to eliminate pure gauge, using judiciously chosen gauge transformation, persists also in the nonlinear case, provided the nonlinearity is SU(2)-symmetric \[13\]. Suppose that a gauge field generates nonzero curvature, i.e., \( F_{mn}(A) \neq 0 \). One can represent \( A(x) = \tilde{A}(x) + a(x) \), where \( \tilde{A} \) is a pure gauge, and hence \( F_{mn}(A) = 0 \) for all \( m \) and \( n \), while \( a \) is a component generating non-zero curvature (both \( \tilde{A}(x) \) and \( a(x) \) are Hermitian). Consider also an orthonormal basis, \( \Phi_{1,2}(x) (\Phi_{1}^\dagger \Phi_{2} = \delta_{ij}) \) in the spinor space consisting of the kernel of the operator \(-i\nabla + A(x)\): \( i\nabla \Phi_j = A \Phi_j \). The existence of such a basis is ensured by the zero-curvature, which is also integrability, condition \( F_{mn}(A) = 0 \), and by the hermiticity of the components of \( A \) \[13\]. Now one can define the unitary 2 \( \times \) 2 matrix solution \( \Phi = (\Phi_1, \Phi_2) (\Phi^\dagger \Phi = \sigma_0 \) where \( \sigma_0 \) is 2 \( \times \) 2 identity matrix) and perform the gauge transformation

\[
\Psi = \Phi U, \quad U(x, t) = (u_1(x, t), u_2(x, t))^T.
\]

The spinor \( U \) solves the equation

\[
\begin{align*}
\partial_t U &= -\frac{1}{2} \nabla^2 U + G(U^\dagger \Phi^\dagger, \Phi^\dagger) U - i\alpha \cdot \nabla U \\
&\quad - \frac{i}{2} (\nabla \cdot \alpha) U + \frac{1}{2} \alpha^2 U + V_0(x) U
\end{align*}
\]

where the transformed gauge field \( \alpha = \Phi^\dagger a \Phi \) originates an effective potential. The spinor \( U \) can be viewed as an envelope, independent of the pure gauge, propagating against stationary "carrier" states \( \Phi_{1,2}(x) \), which do not depend on the curvature. It follows from Eq. (3) that in the case of SU(2)-invariant nonlinearity, \( G(U^\dagger \Phi^\dagger, \Phi^\dagger) = G(U^\dagger, U) \), the presence of a pure gauge, \( \tilde{A} = \tilde{A} \) and \( a = 0 \), does not affect the existence of nonlinear modes, although a spatial profile of a solution – if any solution exists – depends on the gauge field. If, however, \( a \neq 0 \) the equation for the envelope becomes gauge-field dependent, and thus the very existence of the modes can be affected by such a field. For non-SU(2)-invariant nonlinearity, a pure gauge may affect the existence of stationary solutions, but now the nonlinearity becomes \( x \)-dependent.

The solutions \( \Phi_{1,2} \) can be found explicitly in a number of cases. For example, if the components of \( \tilde{A} \) are of the form \( \tilde{A}_{nm} = X_m(x_m) A_m \), where \( X_m(x_m) \) are real-valued functions of one variable, and \( A_m \) are Hermitian matrices simultaneously diagonalizable by a unitary transformation \( S \): \( S^{-1} A_S S = \text{diag}(\lambda_1, \lambda_2) \), then

\[
\begin{align*}
\Phi_1 &= \frac{S}{\sqrt{2}} \begin{pmatrix} 1 & 0 \end{pmatrix} e^{-i\sum \lambda_j \xi_j}, \\
\Phi_2 &= \frac{S}{\sqrt{2}} \begin{pmatrix} 0 & 1 \end{pmatrix} e^{-i\sum \lambda_j \xi_j}
\end{align*}
\]

where \( \xi_j(x_j) = \int X_j(x_j) dx_j \) are the real functions.

If some spatial components of \( \tilde{A} \), considered alone, constitute a pure gauge, the spatial dimensionality of \( a \) can be made less than that of \( \tilde{A} \), and hence less than \( d \). For example, if in the 3D space \( A_1 = A_1(x_1) \) \( [\partial_2 A_1 = \partial_3 A_1 = 0] \) one can choose \( \tilde{A} = (A_1, 0, 0) \), so that \( a = (0, A_2, A_3) \) is a 2D matrix vector in the 3D space. Hence, if there exists a stable nonlinear mode sustained by such gauge field, then there must also exist a stable mode sustained by a gauge field of a lower dimension (see \[21\] for examples) which is obtained by gauging out the respective spatial components of \( \tilde{A} \).

Two-dimensional models— Turning now to the 2D case, we present a variety of examples of self-sustained stable modes sustained by the curvature. To this end we consider \( \tilde{A} = (A_1(x_1) \sigma_1, A_2(x_2) \sigma_1) \), where \( A_1(x_1) \) can be arbitrary functions ensuring the existence of the integrals \( \xi_j \) (and of the matrix \( \Phi \)) defined in (4). Focusing on the simplest (Abelian) case \( [A_n, A_m] = 0 \), we set \( a = (\zeta_1(x_2) \sigma_1, \zeta_2(x_2) \sigma_1) \) where functions \( \zeta_j(x_3 - j) \) are so far arbitrary. In this case \( \alpha = -\zeta_1(x_2) \sigma_3, \zeta_2(x_2) \sigma_3 \) and \( \nabla \cdot \alpha = 0 \). We consider typical nonlinearity

\[
G(\Psi^\dagger, \Psi) = (g|\psi_1|^2 + \tilde{g}|\psi_2|^2, g|\psi_2|^2 + \tilde{g}|\psi_1|^2)^T
\]

where \( g > 0 (\tilde{g} > 0) \) and \( g < 0 (\tilde{g} < 0) \) correspond to repulsive and attractive intra- (inter-) species interactions. If \( \tilde{g} = g \), i.e., \( G(\Psi^\dagger, \Psi) = g\Psi^\dagger \Psi \). Eq. (1) is unitary equivalent to an SU(2)-invariant spinor NLS equation \[13\]. Since the latter does not support stable 2D localized states, a pure gauge also cannot lead to their emergence. However, the picture changes drastically for nonzero curvature \( B \neq 0 \).

First we consider Eqs. (1), (5) with \( \tilde{g} = g \) and without external trapping potential, \( V_0(x) \equiv 0 \). We set \( \tilde{A} = x \) and explore the curvature introduced by a constant field \( B \) generated by \( a = ((1 + B/2)x_2 \sigma_1, (1 - B/2)x_2 \sigma_1) \). In Fig. (1) we show examples of nonlinear states sustained by such curvature [all reported numerical results were obtained for (1)]. A stable fundamental soliton in the medium with attractive nonlinearity is shown in Fig. (1a), (b). More striking results are presented in Fig. (1c)-(f), illustrating stable localized fundamental and vortex-carrying states obtained for repulsive nonlinearity (vortices of a single repulsive gauged NLS equation in a constant magnetic field have been reported in \[63\]). Obviously, such states would not exist without curvature at \( V_0(x) = 0 \), so we term them pseudo-solitons.
Their amplitudes (upper row) feature rotational symmetry, while their phases (middle row) are highly unconventional and have different symmetries for different types of solutions [they are determined by phase structure of $\Phi_1$ or $\Phi_2$ carrier states defined in (1) as discussed below]. The states in Fig. 1 exist as stationary families ($\Psi \propto e^{-i\mu t}$) parameterized by the chemical potential $\mu$ determining the norm of the solution $N = \int d^2x \Psi^\dagger \Psi$. The dependencies $N(\mu)$ for fundamental solitons and pseudo-solitons are presented in Fig. 2(a). In the whole domain of $\mu$ shown, the families of fundamental solitons ($\mu < B/2$, attractive medium) and pseudo-solitons ($\mu > B/2$, repulsive medium) are dynamically stable [the red unstable family in panel (a) corresponds to a “superposition” state discussed below].

Gauge field can sustain localized linear modes, i.e., stationary solutions of (1) at $G \equiv 0$. In our case they are given by $\Psi_j^{\text{fin}} = e^{-i(-1)^j x_1 x_2 - iBt/2 - Bx^2/4} \Phi_j$ with the carrier modes obtained from (4) with the proper matrix $S$: $\Phi_j = \{(1, (-1)^j)^T e^{i(-1)^j(x_1 x_2)/2}/\sqrt{2} \mid j = 1, 2\}$. Both families shown in Fig. 1(a), bifurcate from one of the states $\Psi_j^{\text{lin}}$ (families bifurcating from $\Psi_1^{\text{lin}}$ and $\Psi_2^{\text{lin}}$ coincide). Notice that the existence of the linear limit supported by 1D SOC in a 2D BEC requires strong anisotropy of the limiting solution [21]. In our case the soliton amplitude remains radially symmetric at $\Psi_j \rightarrow \Psi_j^{\text{lin}}, \mu \rightarrow B/2$, reflecting different origin of the phenomenon: now the linear limit is sustained by the curvature induced by the gauge field.

When $\mu \rightarrow -\infty$ (attractive medium) the fundamental soliton approaches Towner soliton [30] with the norm $N \rightarrow N_\text{TF} \approx 5.85$ [see Fig. 2(a)]. The limit $\mu \rightarrow +\infty$ (repulsive medium) is described by the Thomas-Fermi (TF) approximation, which now can be applied even in the absence of external potential. The TF limit for pseudo-solitons belonging to the family bifurcating from $\Psi_j^{\text{lin}}$ has the form $\Psi_j^{\text{TF}} = e^{ix_1 x_2 - i\mu t}(\mu - B^2 x^2/8g)^{1/2} \Phi_1$ and is valid for $|x| < (8\mu)^{1/2}/B$. Maximal amplitude $\psi_1^{\text{max}} = \max_\Psi |\psi_{1,2}|$ of the state in the TF limit is thus $\sim \mu^{1/2}$. This is in qualitative agreement with the increase of soliton amplitude shown in Fig. 2(b) for $\mu > 1/2$. The tendency for contraction of the nonlinear state in the attractive case and its expansion in the repulsive one is illustrated in Fig. 2(c) by the dependence of the integral soliton width $W = \int d^2x (|\Psi^2|)^{1/2}$ on $\mu$.

Families of localized vortex states sustained by the gauge field also have the linear limit. In Fig. 2(d) we show a family bifurcating from the linear state $\Psi_{\text{vort}}^{\text{lin}} = e^{ix_1 x_2 - i3Bt/2 - Bx^2/4} \Phi_1$. One of our central results is that all vortex pseudo-solitons (at $\mu > 3/2$, $g = -1$) as well as vortex solitons (at $1.125 < \mu < 3/2$, $g = -1$) were found dynamically stable [black curves in Fig. 2(d)]. Vortex solitons with $\mu \lesssim 1.125$ in the attractive medium are unstable [red curve in Fig. 2(d)] and usually decay into two rotating fragments that do not fly apart, but perform aperiodic radial oscillations [Fig. 2(g)-(i)].

A role of a pure gauge. Since $\tilde{A}$ can be gauged out and carrier states $\Phi_{1,2}$ are mutually orthogonal, the pure gauge does not affect linear dynamics. Nonlinearity couples the carrier states and since their phases depend on $\tilde{A}$ [see (4)], it can reveal the presence of pure gauge in two ways. First, nonlinear modes from families bifurcating from a superposition of linear states $c_1 \Psi_1^{\text{lin}} + c_2 \Psi_2^{\text{lin}}$ ($c_{1,2}$ are constants) display different spatial symmetries and stability properties. In Fig. 3 we illustrate a stable fundamental soliton [(a),(b)] and pseudo-soliton [(c), (d)] belonging to the families bifurcating from the $\Psi_1^{\text{lin}} + \Psi_2^{\text{lin}}$ state in the attractive and repulsive media, respectively. The $N(\mu)$ dependence for this family exactly coincides with that shown in Fig. 1(a) for solitons bifurcating from either $\Psi_1^{\text{lin}}$ or $\Psi_2^{\text{lin}}$ states. However, now $|\psi_{1,2}|$ distributions are different: amplitude distributions in Fig. 3 reveal the stripe patterns resembling previously known theoretical [27, 31] and experimental [32] results. The stability properties are different too: the family of pseudo-solitons becomes unstable at $\mu \gtrsim 1.05$ [red line in Fig. 2(a)]. Decay of the unstable vortex soliton with $\mu = 1.05$ in the attractive medium. Numerical results shown here and below were obtained for the original system (1) and for $B = 1$.

FIG. 1: Absolute value $|\psi_1|$ (upper row) and phase distributions (middle row) for the fundamental soliton [(a),(b)] in the attractive medium, $g = -1$, and self-trapped fundamental [(c),(d)] and vortex [(e),(f)] pseudo-solitons in the repulsive medium, $g = 1$ (corresponding $\mu$ values are indicated in the plots and by red dots in Fig. 2 below). These are stable and have identical $|\psi_1|$ and $|\psi_2|$ distributions, but different phases. (g)-(i) Decay of the unstable vortex soliton with $\mu = 1.05$ in the attractive medium. Numerical results shown here and below were obtained for the original system (1) and for $B = 1$. [Image 317x504 to 357x504]
bifurcating from the state \( \Psi_{\text{lin}} \).

Decay of the unstable pseudo-soliton of this type at \( \mu = 0 \), and repulsive (c),(d), \( \mu > \frac{1}{2}, g = +1 \), and norm of vortex solitons and vortex pseudo-solitons (d) vs \( \mu \). The \( N(\mu) \) curves for families bifurcating from \( \Psi_{\text{lin}}^{\text{lin}} \) coincide. The curves in (a) also exactly coincide with those for solitons bifurcating from the linear superposition \( \Psi_{\text{lin}}^{\text{lin}} + \Psi_{\text{lin}}^{\text{lin}} \). They also coincide with families obtained for non-SU(2)-symmetric nonlinearities \( g = -1.4, \tilde{g} = -0.6 \) (at \( \mu < 1/2 \)) and \( g = 1.4, \tilde{g} = 0.6 \) (at \( \mu > 1/2 \)). The family bifurcating from \( \Psi_{\text{lin}}^{\text{lin}} + \Psi_{\text{lin}}^{\text{lin}} \), however, is unstable at \( \mu \gtrsim 1.05 \) [indicated by red curve in (a) coinciding with stable branch for the family bifurcating from \( \Psi_{\text{lin}}^{\text{lin}} \)]. Stable (unstable) families are shown black (red).

FIG. 3: Absolute values \(|\psi_{1,2}|\) for solitons and pseudo-solitons bifurcating from the state \( \Psi_{\text{lin}}^{\text{lin}} + \Psi_{\text{lin}}^{\text{lin}} \) in the attractive (a),(b), \( \mu = 0 \), and repulsive (c),(d), \( \mu = 2 \), media, respectively. (e),(f) Decay of the unstable pseudo-soliton of this type at \( \mu = 1.4 \) in the repulsive medium.

FIG. 2: Norm \( N(a) \), maximal amplitude \( \psi_{1,2}^{\text{max}}(b) \), and integral width \( W(c) \) of the fundamental solitons (\( \mu < 1/2 \), \( g = -1 \)) and pseudo-solitons (\( \mu > 1/2 \), \( g = +1 \)), and norm of vortex solitons and vortex pseudo-solitons (d) vs \( \mu \). The \( N(\mu) \) curves for families bifurcating from \( \Psi_{\text{lin}}^{\text{lin}} \) coincide. The curves in (a) also exactly coincide with those for solitons bifurcating from the linear superposition \( \Psi_{\text{lin}}^{\text{lin}} + \Psi_{\text{lin}}^{\text{lin}} \). They also coincide with families obtained for non-SU(2)-symmetric nonlinearities \( g = -1.4, \tilde{g} = -0.6 \) (at \( \mu < 1/2 \)) and \( g = 1.4, \tilde{g} = 0.6 \) (at \( \mu > 1/2 \)). The family bifurcating from \( \Psi_{\text{lin}}^{\text{lin}} + \Psi_{\text{lin}}^{\text{lin}} \), however, is unstable at \( \mu \gtrsim 1.05 \) [indicated by red curve in (a) coinciding with stable branch for the family bifurcating from \( \Psi_{\text{lin}}^{\text{lin}} \)]. Stable (unstable) families are shown black (red).

FIG. 4: Norm \( N(a) \) and integral width \( W(c) \) vs \( \mu \) for fundamental solitons in the expulsive parabolic trap with \( \omega_0 = 8^{-1/2} \).

Solitons in expulsive trap.— Striking effect of a gauge field on 2D stable localized modes is observed in a medium with either attractive or repulsive SU(2)-invariant nonlinearity in the presence of an expulsive parabolic trap \( V_0(x) = -\omega_0^2 x^2 \). We consider spatially-dependent radially symmetric field \( B = \omega_0^2 x^2 \) generated by \( a = (\omega_0^2/3)(-x_1^2,x_2^2) \). Families of the localized solutions, bifurcating from the time-independent linear mode with \( \mu = 0 \) are shown in Fig. 4(a). Surprisingly, stable solitons with relatively small amplitudes were found even in the attractive medium, while pseudo-soliton family (repulsive medium) is always stable. Notice that unstable solitons in the attractive medium now may have the norm exceeding norm \( N_T \) of the Townes soliton. In Fig. 5 we show the structure of stable fundamental pseudo-soliton in the expulsive potential. The distributions \(|\psi_{1,2}|\) are radially symmetric and identical, while the four-fold symmetry introduced by the gauge field dictates the symmetry of phase distributions of the first [panel 5(b)] and second [panel 5(c)] components. Remarkably, the system supports also solutions with the four-fold symmetric amplitude distributions. For example, a nonlinear family of such solutions bifurcate from a (time-independent) linear state \( \Psi_{\text{lin}}^{\text{lin}} = (1,-1)^T e^{i\pi/2}/2-\omega_0^2(x_1^2+x_2^2)/12 \). Vortex solitons and pseudo-solitons exist in expulsive traps as well.
Conclusions.— We have shown that gauge fields can dramatically affect stability and, when they generate nonzero curvature, the very existence of localized modes. The effect of a gauge field can be "decomposed" into two parts. Pure gauge is responsible for time-independent carrier states and affects soliton stability. The component having nonzero curvature determines the types of the localized solutions and possible evolution scenarios. These phenomena were illustrated on the examples of two-dimensional solitons in attractive media and pseudosolitons in repulsive media. Nonlinear modes sustained by gauge fields with nonzero curvature were found even in the presence of repulsive potentials. The approach can be employed for creation of 3D stable localized states, generating multidimensional modes in systems with integer pseudospin, investigation of the impact of operating multidimensional modes in systems with integer
