OBJECTIVE — Impaired muscular mitochondrial function is related to common insulin resistance in type 2 diabetes. Mitochondrial diseases frequently lead to diabetes, which is mostly attributed to defective β-cell mitochondria and secretion.

RESEARCH DESIGN AND METHODS — We assessed muscular mitochondrial function and lipid deposition in liver (hepatocellular lipids [HCLs]) and muscle (intramyocellular lipids [IMCLs]) using 31P/1H magnetic resonance spectroscopy and insulin sensitivity and endogenous glucose production (EGP) using hyperinsulimemic-euglycemic clamps combined with isotopic tracer dilution in one female patient suffering from MELAS (myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) syndrome and in six control subjects.

RESULTS — The MELAS patient showed impaired insulin sensitivity (4.3 vs. 8.6 ± 0.5 mg·kg⁻¹·min⁻¹) and suppression of EGP (69 vs. 94 ± 1%), and her baseline and insulin-stimulated ATP synthesis were reduced (7.3 and 8.9 vs. 10.6 and 12.8 ± 1.3 μmol·kg⁻¹·min⁻¹) compared with those of the control subjects. HCLs and IMCLs were comparable between the MELAS patient and control subjects.

CONCLUSIONS — Impairment of muscle mitochondrial fitness promotes insulin resistance and could thereby contribute to the development of diabetes in some patients with the MELAS syndrome.

mode) and the time domain fit routine AMARES (advanced method for accurate, robust, and efficient spectral fitting of MRS data). Aerobic plantar flexion exercise was performed at 50% maximal contraction until fatigue. PCr amplitudes were fitted to a mono-exponential curve using nonlinear least squares. Ectopic lipids were measured with \(^1\)H-MRS (2). The patient's PCr recovery was compared with that of healthy male subjects from a previous study of ours (3), and REE was compared with the value predicted by the Harris-Benedict equation for women: 
\[
(66.5 \times 1.8 + \text{height} - (4.7 \times \text{age}) - 1.7)
\]
All other tests were performed on the patient and six control subjects (CON), and data are shown as means ± SEM.

**RESULTS**

Glucose and FFA metabolism

The MELAS patient had normal fasting EGP (1.7 vs. 1.7 ± 0.1 mg·kg\(^{-1}\)·min\(^{-1}\)), plasma FFA (385 μmol/l), and insulin suppression of lipolysis (95%) in comparison with the control subjects. EGP suppression (69 vs. 94 ± 1%) and M (4.3 vs. 8.6 ± 0.5 mg·kg\(^{-1}\)·min\(^{-1}\)) were markedly lower in the patient than in the control subjects (Fig. 1A).

Energy expenditure

The patient's respiratory quotient was 0.88, indicating reliance on glucose oxidation during fasting. REE was lower than predicted (1,108 vs. 1,355 kcal/24 h). Maximal power (88 W) and \(\overline{V}O_2\)max (19.4 mg·kg\(^{-1}\)·min\(^{-1}\)) were reduced by ~40% compared with those in healthy volunteers studied under identical conditions (5). HCLs, albeit within the normal range (≤5%) (6), were higher in the MELAS patient than in the control subjects, whereas IMCLs were similar (Fig. 1D).

**CONCLUSIONS** — The MELAS patient exhibited severe reductions in ATP concentrations and synthesis at baseline, after exercise, and during insulin stimulation. This was paralleled by muscular and hepatic insulin resistance. While the cause of insulin resistance could likely be explained by primary defects of mitochondrial number and fitness, both abnormalities could also result from lipotoxicity. Lipotoxicity can cause not only β-cell dysfunction but also muscular insulin resistance via inflammatory pathways, decreasing fat oxidation and raising IMCLs (7). Normal fasting and insulin suppression of FFA as well as low IMCLs would argue against the operation of lipotoxicity in our patient. However, her severe hepatic insulin resistance and higher HCLs are in line with the contention that hepatic signals, e.g., release of lipids (6), contributed to muscular insulin resistance and mitochondrial dysfunction. Finally, despite good long-term metabolic control, chronic hyperglycemia could have aggravated insulin resistance and mitochondrial dysfunction via glucotoxicity.

Similar to most MELAS patients, our patient had normal body mass, manifested diabetes in early adulthood, and required insulin treatment (8). Although some studies found that patients with mitochondrial diabetes are insulin resistant (8), others reported normal insulin sensitivity, suggesting that the A3243G mutation in skeletal muscle does not play a causative role in diabetes development (9). As the majority of studies show that MELAS patients present with impaired glucose-stimulated insulin secretion, occurrence of diabetes has been attributed to impaired β-cell function, which strongly depends on intact mitochondrial metabolism (7). Our patient presented with severe insulin resistance, impaired insulin-stimulated glucose transport/phosphorylation, reduction of myocellular concentrations, and synthetic flux of ATP. These alterations are similar to findings in insulin-resistant populations (elderly, obese nondiabetic humans, and first-degree relatives of patients with type 2 diabetes) who are at increased risk of diabetes (10,11). Previous reports found...
increased prevalence of A3243G in patients with type 2 diabetes (12). Thus, insulin resistance along with lower muscular mitochondrial fitness could contribute to the manifestation of diabetes in MELAS patients.

In conclusion, impairment of muscle mitochondrial fitness contributes to insulin resistance in our patient with MELAS and diabetes, which resembles the mechanism described for first-degree relatives of type 2 diabetic patients. However, given the broad spectrum of MELAS defects and heterogeneity of insulin sensitivity in these patients, the present report does not permit the conclusion that MELAS is a typical model for the pathogenesis of type 2 diabetes.
