(March 24, 2022)

Recent reports about observations of superconductivity in PrBa$_2$Cu$_3$O$_7$ raise a number of questions: (i) of various theories striving to explain the $T_c$ suppression in Pr$_x$Y$_{1-x}$Ba$_2$Cu$_3$O$_7$, are there any compatible with possible superconductivity in stoichiometric PrBa$_2$Cu$_3$O$_7$? (ii) if this superconductivity is not an experimental artifact, are the superconducting carriers (holes) of the same character as in the other high-$T_c$ cuprates, or do they represent another electronic subsystem? (iii) is the underlying mechanism the same as in other high-$T_c$ superconductors? I present an answer to the first two questions, while leaving the last one open.

One of the most exciting cases of superconductivity suppression in high-$T_c$ cuprates is that of $RE_{1-x}Pr_x$Ba$_2$Cu$_3$O$_7$, where $RE$ stands for a rare earth (see Refs. [8] for reviews). Even more exciting are recent indications that conductivity and superconductivity can be restored in pure stoichiometric PrBa$_2$Cu$_3$O$_7$ [6,7]. This is such an unexpected result that it is still not generally accepted and further experimental confirmation is required. Nevertheless, this fact was reported by two independent groups, and it is time now to understand the theoretical consequences of this finding. The most important message, if this finding is true, is that at $x = 1$, and, presumably, at intermediate $x$‘s, there are free carriers in $RE_{1-x}Pr_x$Ba$_2$Cu$_3$O$_7$, and the suppression of metallic conductivity at sufficiently large $x$ must be due to localization of those carriers. This statement effectively eliminates the possibility of hole depletion due to hole transfer into occupied states (“four-valent Pr model”). It furthermore becomes highly unlikely that any kind of magnetic pair breaking is in effect, because (1) normal state conductivity drops sharply with doping, indicating the change of character, if not the number, of carriers, and (2) superconductivity is, supposedly, restored at $x = 1$. It seems that we can then consider only the models which associate the (super)conductivity suppression with a transfer of holes to an itinerant, but different from the undoped YBCO, state, which should furthermore be prone to localization. At first glance the only theoretical model that satisfy this criterion is the itinerant model of Liechtenstein and Mazin [17]. I will show below that contrary to the claim in the Fehrenbacher and Rice paper [8] (FR), their model is also compatible with metallic and possibly superconducting behavior in PrBa$_2$Cu$_3$O$_7$.

In fact, it turns out that the difference between the “local” FR model and the “itinerant” LM model is much smaller than it was thought to be; if handled correctly, the FR model never renders localized states. This new understanding means that the physics of superconductivity suppression and its possible recovery is essentially the same in both model. There is still a quantitative difference between the two, which is hard to access experimentally, but which is now of limited importance. A generic model that can be nicknamed FRLM explains the entire body of existing experimental results and does not seem to have any sensible alternative. An exciting fact is that this generic model not only provides a possibility for metallic and superconducting behavior of PrBa$_2$Cu$_3$O$_7$, but that it also predicts the superconducting holes in it to be of entirely different physical nature than the carrier in familiar high-$T_c$ superconductors.

Let me start with a brief reminder of the essence of the FR model. The crystal structure of the YBCO family cuprates is such that a rare earth ion and four nearest oxygens form a nearly perfect cube. Moreover, among 7 orbitals of $f$-symmetry there is one, $xyz$, which has eight equivalent lobes directed along eight directions $[\pm 1, \pm 1, \pm 1]$. In the standard coordinate system where $x$, $y$ correspond to the CuO bond directions the same orbital is $(x^2-y^2)z$. Since this $f$-orbital extends directly towards neighboring oxygens, one expects a noticeable $p\sigma f\sigma$ hopping between $RE$ and $O$. Thus the electronic structure of a $RECu_2O_4$ bilayer breaks into two weakly interacting subsystems: usual Cu-O $p\sigma d\sigma$ bands, of which two antibonding ones cross the Fermi level in YBCO, and RE-O $f\sigma d\sigma$ states. Oxygen $p$ states directed along the Cu-O bonds (“$p\sigma$” orbitals) participate in the former and those perpendicular to the bonds (“$p\pi$” orbitals) in the latter. If we start with a cluster of one Pr and eight surrounding oxygens and considered formation of an antibonding state of the $f(x^2-y^2)$, $Pr$ orbital and eight oxygen $p$ orbitals pointing directly towards Pr, we find one bonding, one antibonding, and 6 non-bonding states. If the energy difference between the bare O $p$ level and bare Pr $f$ level is not too large, the energy of this antibonding state, $p\sigma f\sigma^*$, may become higher than that of the $p\sigma d\sigma$ $Cu$-$O$ state and will pull some holes out of the latter. Whether or not this will happen depends on the $p-f$ energy separation and the $p-f$ hopping integral. Suppression of superconductivity in $RE_{1-x}Pr_x$Ba$_2$Cu$_3$O$_7$ is thus ascribed to the hole transfer from the superconducting $p\sigma d\sigma^*$ band into the $p\sigma f\sigma^*$ state. An indispensable component of this model is localization of carriers promoted into the $p\sigma f\sigma^*$ state. FR [8] argued that the oxygen orbitals forming this state form the 45$^\circ$ angle with the CuO planes and thus the orbitals of the same oxygen pointing towards neighboring Pr ions are orthogonal to each other. They also neglected direct hopping between the oxygen $p\pi$ orbitals. In such an approximation...
the effective bandwidth of the $pf\sigma^*$ band is zero, and the holes there are localized by infinitesimally small disorder. This was the original explanation of the lack of (super)conductivity in PrBa$_2$Cu$_3$O$_7$. Furthermore, since this model renders noticeable presence of Pr states at the Fermi energy, one expects the Curie temperature for ordering of the Pr moments to be much higher than for other $RE$Ba$_2$Cu$_3$O$_7$, which is indeed the case. A drawback is that total localization in the FR model does not let the given Pr$_6$S$_8$ cluster be influenced in any direct way by the rare earths filling other cells, in contradiction with the experiment: the $T_c$ suppression rate even at low doping depends strongly on the host rare earth.

The LM model differs from the FR model in essentially only one aspect: direct hopping between oxygen orbitals is taken into account. LM calculated this hopping as well as other relevant parameters of the electronic structure numerically using LDA+U method including Coulomb correlation in the rare earth $f$-shell. They found substantial O-O hopping so that independent orbitals $\{10\}$ is taken into account. LM calculated doping depends strongly on the host rare earth.

Interestingly, it was not noticed until very recently that the geometric argument of FR was incorrect: in fact, the angle that an O-Pr bond forms with the CuO$_2$ planes is not 45°, but $\tan\left(1/\sqrt{2}\right) \approx 35.2°$, which means that even in the FR limit of no direct O-O hopping, the $pf\sigma^*$ states form a band whose dispersion is defined by the Pr-O hopping amplitude $t_{pf\sigma}$. Below I show how this band forms, using the nearest-neighbor tight-binding Hamiltonian. Let us begin with some notations: first, we neglect the (very small) $z$-dispersion. (This means that all orbitals we consider are antisymmetric with respect to $z \rightarrow -z$ reflection, like the $f_{z}(x^2-y^2)$ orbital.) Then the two plane problem is equivalent to a single plane. If we include all nearest neighbors, the following orbitals contribute to the FR band: $Pr \ z(x^2-y^2)$, $O_2 \ z$, $O_3 \ z$, $O_2 \ y$, $O_3 \ x$, Cu $xy$, Cu $yz$, and (8) Cu $zx$. Their in-plane 2D symmetries are, respectively, $x^2-y^2$, $s$, $s$, $y$, $x$, $xy$, $y$, and $x$, which simplifies the task of the tight-binding description of the band structure. Let us now identify the largest hopping amplitudes between these orbitals. According to FR, this is $pf\sigma$, which we shall denote $t_{pf}$. It controls the following hopings: $t_{12} = t_{13} = \sqrt{\frac{5}{27}}t_{pf}$, $t_{14} = t_{15} = \sqrt{\frac{2}{27}}t_{pf} = \sqrt{2}t_{12}$. This parameter defines the effect of the rare earth substitution on the FR band. Another hopping, which is the strongest according to LM, is of $pd\pi$ type, denoted $t_{pd}$. The hopping amplitudes $t_{28}$, $t_{37}$, $t_{46}$, and $t_{58}$ all are equal to $t_{pd}$. This parameter defines the dispersion of the FR band in the absence of the $f$ states; e.g., in YBa$_2$Cu$_3$O$_7$, or in the spin-minority channel of PrBa$_2$Cu$_3$O$_7$. Let us first consider these two hopings separately.

The FR model corresponds to an approximation $t_{pd} = 0$. Dispersion of the oxygen $p\pi$ states is completely neglected; an isolated Pr impurity forms a localized antibonding state, shifted up with respect to the bare $O\ p$ level by

$$\epsilon_k - \epsilon_p = \delta \epsilon = \frac{5}{9} \frac{8t_{pf}^2}{E_p - E_f}, \tag{1}$$

where 8 stands for the eight neighboring oxygens. It is assumed that $t_{pf} \ll E_p - E_f$. In the opposite limit, when all rare earth sites are occupied by Pr, a narrow band is formed with the dispersion

$$\epsilon_k - \epsilon_p = \delta \epsilon - \delta \epsilon \cos 2\varphi (\cos ak_x + \cos bk_y)/2, \tag{2}$$

where $\varphi = \arctan(1/\sqrt{2})$ is the angle that the Pr-O bond forms with the $xy$ plane. Had this angle been 45°, as assumed by FR, the band would be dispersionless and thus fully localized. In reality, it should acquire a finite bandwidth $W = \delta \epsilon \cos 2\varphi = \delta \epsilon/3$, even were without Pr. This is an example of dispersion due to nonorthogonality: the Hamiltonian written in terms of the oxygen orbitals pointing towards Pr is diagonal, but such a basis is nonorthogonal and that results in dispersion. Note that the top of the band occurs at the $(\pi, \pi)$ point and that is where the holes go from the $pd\pi$ superconducting band. Fig. illustrates that indeed at this point the $pf\sigma$ interaction is antibonding along all bonds. Now we consider the case of finite $t_{pd}$ and no $f$ states. For simplicity, we let the energy of the Cu $d$ level be the same as the energy of the O $p$ level. Then four $O\ p$ orbitals and three Cu $d$ orbitals form three antibonding bands (besides the bonding and nonbonding bands):

$$\epsilon_k - \epsilon_p = 2t_{pf} \sin \frac{ak_x}{2}, \tag{3}$$

$$\epsilon_k - \epsilon_p = 2t_{pf} \sin \frac{bk_y}{2}, \tag{4}$$

$$\epsilon_k - \epsilon_p = 2t_{pd} \sqrt{\sin^2 \frac{ak_x}{2} + \sin^2 \frac{bk_y}{2}}. \tag{5}$$
The top of the highest (third) band is again at \((\pi, \pi)\), as illustrated in Fig. 1, showing again the antibonding interactions for all bonds.

The case of \(pd\pi\) and \(pf\sigma\) interactions taken together cannot be solved analytically. Before reporting the numerical results, we make one additional observation: since both cases separately produce dispersive bands with the maximum at \((\pi, \pi)\), one might expect this effect (band dispersion) to be enhanced when both interaction are included. One can easily see (Fig.1) that this is not true: the configuration of the O \(p\) orbitals, which is antibonding in the first case, is nonbonding in the second case, and vice versa.

The main shortcoming of the original FR model was its inability to describe the different rate of \(T_c\) suppression with the different rare earth hosts. The LM model with its dispersive \(pf\sigma\) provides a natural explanation. However, we can see comparing Eqs.(2) and (4), that at low doping, that is near the \((\pi, \pi)\) point, the shape of the FR band is very similar to that of the LM band. Note that the scale of the dispersion, i.e. the effective masses, may be different — the FR band should be heavier than the LM band and thus easier to localize. However, for the ideal stoichiometric \(\text{PrBa}_2\text{Cu}_3\text{O}_7\) at zero temperature both models give a metal and possibly a superconductor.

Another indirect argument in favor of the LM model over the FR model was deduced from recent near-edge X-ray absorption experiments[12]. It was found that O \(p_z\) orbitals form a relatively small angle with the CuO_2 planes: 20 to 25° at the doping level of 80\% Pr. This is closer to the prediction of the LM model [7] (15 to 18°) than to the original FM prediction [3] (45°), and even to the corrected number of 36°. However, the fact that the correct FR model is nonorthogonal not only yields a finite bandwidth in pure \(\text{PrBa}_2\text{Cu}_3\text{O}_7\), but also makes the average angle of the O \(p_z\) orbitals dependent on doping at small doping — similar, but quantitatively different from the prediction of the LM model.

Indeed, the orbitals around an isolated Pr impurity are tilted by \(\varphi = \arctan(1/\sqrt{2})\); it is however obvious that if an oxygen atom has Pr ions on both sides, the highest state does not include \(O(p_z)\) character of this oxygen at all. In the low doping limit, for the Pr concentration \(x\), the probability for an oxygen to have 1 Pr neighbor is \(\nu_1 = 2x(1-x)\), and to have 2 neighbors is \(\nu_2 = x^2\). Thus the average \(p_z\) character for the in-plane oxygen holes, seen in an experiment like Ref. [12] is \(p_z = \nu_1 \sin^2 \varphi\), while the total number of the holes in the FR state is \(n = \nu_1 + \nu_2\). The average tilting angle is thus \(\sin^2 \alpha = 4(1-\alpha)\). For \(x = 0.8\) we find \(\alpha \approx 19.5^\circ\), in excellent agreement with the experiment. Moreover, this number is the lower bound on \(\alpha\) in the FR model, because at large \(x\) one cannot neglect dispersion of the FR band, which will force \(\alpha\) to deviate from the formula above (at \(x = 1\) the FR model should give the same number as the LM model, which is \(\frac{7}{9}\) about 20°), so that at \(x = 0.8\) we find \(\alpha \geq 20^\circ\). Interestingly, while both the FR and LM models predict a dependence of the angle on concentration, and both must give the same value at \(x = 1\) (\(\alpha\) does not depend on the effective mass at this point), they predict the opposite dependences: in the LM model \(\alpha\) falls to zero when \(x \to 0\), while in the FR model it increases up to \(\alpha = \varphi \approx 36^\circ\).

My conclusion is that after being corrected to take into account the right geometry of the Pr-O bonds, the FR model provides better agreement with the experiment than the LM model. I emphasize that after such correction the difference between the two models is not the difference between a band model and a localized model, but the difference between two band models, one where dispersion originates from the \(pf\sigma\) Pr-O hopping, and another where it appears mostly due to the \(pd\pi\) Cu-O hopping. The fact that the former appears more successful (however, the final word will be said by an experiment accessing \(x\) dependence of the angle \(\alpha\)), does not mean that the \(pd\pi\) hopping is negligibly small. As illustrated on Fig.1c, it merely means that the dispersion due to this hopping is weaker than that due to \(tpf\sigma\).

To summarize, current experimental situation in \(\text{Pr}_x\text{RE}_{1-x}\text{Ba}_2\text{Cu}_3\text{O}_7\) is such that the band version of the Fehrenbacher-Rice model presented here explains all existing experiments addressing superconducting and transport properties of this system, including the recent observation of superconductivity at full substitution. In fact, \(\text{PrBa}_2\text{Cu}_3\text{O}_7\) is a more novel superconductor than all other cuprate high \(T_c\) materials known: it is the only one where superconducting carriers are not residing in the \(\text{Cu}(x^2-y^2)-O(p_x)\) bands, but are of entirely different character.
