Received 12 May 2008/Returned for modification 23 June 2008/Accepted 15 August 2008

The efficiency of cross-presentation of exogenous antigens by dendritic cells (DCs) would seem to be related to the level of antigen escape from massive degradation mediated by lysosomal proteases in an acidic environment. Here, we demonstrate that a short course of treatment with chloroquine in mice during primary immunization with soluble antigens improved the cross-priming of naïve CD8\(^+\) T lymphocytes in vivo. More specifically, priming of chloroquine-treated mice with soluble ovalbumin (OVA), OVA associated with alum, or OVA pulsed on DCs was more effective in inducing OVA-specific CD8\(^+\) T lymphocytes than was priming of untreated mice. We conclude that chloroquine treatment improves the cross-presentation capacity of DCs and thus the size of effector and memory CD8\(^+\) T cells during vaccination.

Cross-presentation refers to the ability of antigen-presenting cells (APCs) to present exogenous antigens to CD8\(^+\) T cells. This process has been shown to play a crucial role in priming CD8\(^+\) T-cell-dependent responses against soluble, cell-associated, or pathogen-derived antigens which are not directly expressed by APCs (5, 7, 25, 55, 57). Among APCs, dendritic cells (DCs) are the most efficient at inducing antigen-specific immune responses and the only cells adept in cross-priming (3, 13, 41). They use receptor-independent pinocytosis, macropinocytosis, and phagocytosis as well as a range of receptor-mediated mechanisms to acquire and cross-present antigens (37, 52). The intracellular pathways for exogenous antigen presentation are strictly regulated in DCs, and several studies have been aimed at dissecting these processes and characterizing factors and potential modulatory mechanisms affecting cross-presentation (2, 11, 12, 17, 18, 22, 24).

It has recently been demonstrated that cross-presentation of soluble antigens to CD8\(^+\) T cells was effectively improved by inhibiting the endosomal acidification of DCs with NH\(_4\)Cl or chloroquine in vitro (1, 22). Both chloroquine and NH\(_4\)Cl are lysosomotropic agents, which diffuse across the membrane and inhibit intravesicular acidification, which is critical to activating several acid proteases that induce proteolysis of antigens in the endocytic compartments (52, 58). Chloroquine has long been used to increase the efficiency of DNA transfection by inhibiting degradation of DNA absorbed by the cells (31) and has been further reported to cause direct lysosomal membrane permeabilization (6). Accapezzato et al. (1) have recently shown that the administration of a booster dose of anti-hepatitis B virus vaccine, associated with a short course of chloroquine treatment in vivo, significantly enhanced the recall of antigen-specific memory CD8\(^+\) T cells in healthy individuals compared to the group not treated with chloroquine. Altogether, these data highlighted that the efficiency of cross-presentation would seem to be directly related to the level of antigen escape from destruction by endosomal/lysosomal proteolysis and to the ensuing export of the appropriate proteasome-substrates into the class I processing pathway (1, 2, 12, 22, 39, 46, 56). However, the correlation of the antigen escape from degradation mediated by drugs with the efficiency of cross-priming of naïve T cells remains to be assessed.

Here, we have evaluated the efficacy of chloroquine treatment in inducing a primary immune response in mice upon injection of soluble chicken ovalbumin (OVA) alone, OVA associated with alum, or OVA pulsed on DCs. Overall, our results clearly indicate for the first time that short-course treatment of mice with drugs such as chloroquine, aimed at reducing antigen degradation in the endocytic compartments of DCs, improves the priming of naïve CD8\(^+\) T-cell responses against soluble antigens in vivo.

MATERIALS AND METHODS

Mice. Female C57BL/6J mice (H-2\(^b\)) were obtained from Charles River, Calco, Italy, and maintained at the Istituto Superiore di Sanità according to the institutional guidelines. The T-cell-receptor-transgenic mouse line OT-I, expressing a T-cell receptor recognizing an H-2\(^b\)-restricted OVA\(_{257-264}\) epitope, SIINFEKL, was kindly supplied by M. Bellone (San Raffaele Scientific Institute, Milan, Italy). For all experiments, mice between the ages of 6 and 12 weeks were used.

DCs. DCs from spleens of naïve mice were purified as described previously (51). Briefly, spleen fragments were digested for 25 min at room temperature with collagenase and DNase (Sigma). EDTA (5 mM, pH 7.2; Sigma) was added for an additional 5 min to allow disruption of DC–T-cell complexes. After 2 h of incubation at 37°C in tissue culture-treated dishes, nonadherent cells were removed by gentle pipetting and the adherent cells were cultured overnight in DCs media.

Mouse immunization. (i) With free soluble protein. Mice were injected intravenously (i.v.) with different concentrations of soluble OVA and treated subcutaneously (s.c.) with 800 \(\mu\)g of chloroquine 2 h before and 6 h after priming.
ii With alum-OVA. Mice were immunized once by intraperitoneal (i.p.) injection of 200 μg of OVA protein adsorbed onto aluminum hydroxide adjuvant (Alum; Sigma). These mice were treated s.c. with 800 μg of chloroquine 2 h before and 6 h after priming.

iii With OVA-loaded DCs (OVA-DCs). Splenic DCs (5 × 10^6/ml) were pretreated with 20 μM of chloroquine (Sigma Chemical Co.) for 30 min or medium alone, followed by the addition of soluble OVA (3 to 5 mg/ml; grade V; Sigma) or 1 μg/ml of SIINFEKL peptide. Alternatively, DCs were pretreated with chloroquine, with 30 ng/ml of phorbol myristate acetate (PMA), or with both chloroquine and PMA, followed by the addition of soluble OVA. After 1 h of incubation at 37°C, extensive washes, and a 2-h chase, in the continuous presence or absence of chloroquine, 5 × 10^5 cells were used to immunize mice. Mice receiving chloroquine-treated OVA-DCs were treated s.c. with 800 μg of chloroquine 2 h before and 6 h after priming.

Cross-presentation assays in vitro. OT-I cells were isolated from the spleen and lymph nodes of OT-I mice and further enriched for CD8+ T cells by treatment with monoclonal antibodies (MAbs) to CD4 (GK1.5) and major histocompatibility complex (MHC) class II (TIB120), followed by sheep anti-mouse and sheep anti-rat Dynabeads (Dynal A.S., Oslo, Norway). The final preparations from the lymphoid organs contained 75 to 85% CD8+ T cells. For presentation of soluble OVA, purified DCs were suspended in serum-free RPMI at a concentration of 4 × 10^5 cells/ml and preincubated for 30 min at 37°C with or without different concentrations of chloroquine (2 μM, 6.5 μM, and 20 μM), followed by the addition of OVA (0.5 mg/ml) or 1 μg/ml of SIINFEKL peptide. After 1 h of incubation at 37°C, the cells were washed, added to microtiter plates, and incubated with 10^5 OT-I T cells, in the continuous presence or absence of chloroquine. The cells were incubated for 72 h, and 1 μl/well [3H]thymidine (Amersham Biosciences, United Kingdom) was added 12 to 15 h before harvest. Data were shown as mean cpm of triplicate wells minus mean cpm of corresponding control wells in the absence of antigen.

In vivo proliferation assays. For analysis of in vivo proliferation, the enriched OT-I cells were labeled with 5- (and 6-)carboxyfluorescein diacetate, succinimidyl ester (CFSE), as previously described (32). Briefly, semi-purified OT-I cells, as described above, were resuspended in PBS containing 0.1% bovine serum albumin (Sigma) at 10^7 cells/ml and incubated with CFSE (Molecular Probes) at 5 μM for 10 min at 37°C. Cells were subsequently washed in PBS and then transferred via tail vein injection to C57BL/6 mice (2 × 10^5 cells/mouse) that were subsequently primed 1 day later with different concentrations of soluble OVA or OVA-DCs. Three days after priming, these mice were euthanized and cells from pooled axillary, mediastinal, and inguinal lymph nodes were isolated and stained with anti-CD8-phycocerythrin (PE) for flow cytometry analysis.

In vitro cytotoxic assays. Spleens were removed surgically 9 days after priming and prepared as a single-cell suspension. Splenocytes were stimulated in vitro for 5 days with a 2:1 ratio of splenic APCs taken from naïve mice that were pulsed for 90 min with 0.1 mM SIINFEKL peptide and then washed and gamma irradiated. Effector cells were then assayed for cytotoxic activity on 3HCr-labeled EL4 target cells pulsed or not with SIINFEKL peptide at the indicated effector/target ratios. The amount of 3HCr released was determined by gamma counter, and the percent specific lysis was calculated from triplicate samples as follows: [(experimental cpm − spontaneous cpm)/(maximal cpm − spontaneous cpm)] × 100. Spontaneous release was determined from target cells incubated in the absence of effector cells and was <5% in all experiments.

Detection of OVA-specific antibodies. Serum was collected from individual mice on day 14 after immunization with alum-OVA, and anti-OVA antibody titers were determined by enzyme-linked immunosorbent assay. Briefly, 96-well plates (Nunc-Imunno) were coated by overnight incubation at 4°C with 100 μl of PBS containing OVA at 40 μg/ml. Plates were blocked with 1% bovine serum albumin in PBS for 2 h, and serial twofold dilutions of serum samples in PBS were added to the wells. After a 2-h incubation, plates were then washed with PBS containing 0.05% Tween 20 and incubated for 1 h at room temperature with alkaline phosphatase-conjugated goat anti-mouse immunoglobulin G (IgG), IgG1, or IgG2a antibodies (Southern Biotechnology Associates). After three additional washes, the plates were then incubated with p-nitrophenyl phosphate (Sigma) for 1 h at room temperature. Absorbance was read at 405 nm with a microplate reader (Bio-Rad).

Virus challenge. The recombinant influenza A virus WSN/OVA-1, which expresses the SIINFEKL epitope, was previously generated by reverse genetics (50) and grown on Madin-Darby canine kidney cells. Mice were anesthetized with 2.2-trichloroethanol (Avertin) before intranasal challenge with 8 × 10^6 PFU of WSN/OVA-1 virus and euthanized 7 days postinfection.

Intracellular IFNγ staining. Cells derived from spleens and pooled mediastinal lymph nodes (MLN) of infected mice were cultured for 2 h in 96-well U-bottomed plates at 37°C in the presence or absence of 10 μM OVA257-264 peptide (20). Brefeldin A (10 μg/ml) was added to each well, and the cells were incubated for an additional 4 h. The responder cells were then washed twice in brefeldin A-containing PBS (PBS-brefeldin A), treated with MAb to the FeγIII/II receptor to block nonspecific antibodies, and stained with a rat anti-mouse CD8-fluorescein isothiocyanate (FITC) MAb (Pharimgen). The cells were then washed again with PBS-brefeldin A, fixed in 1% formaldehyde in PBS for 20 min, washed in PBS, placed in 0.5% saponin (Sigma) in PBS for 20 min, and incubated with a rat anti-mouse IFNγ–PE MAb (Pharmingen) or a rat IgG1-PE control MAb. Samples were then examined by FACS Calibur flow cytometry.

Tetramer staining. The MHC class I peptide tetramer, SIINFEKL-Kb, conjugated to PE, was synthesized by Proimmune Limited (Oxford, United Kingdom). Bulk spleen cells (5 × 10^7) were stained with PE-conjugated SIINFEKL-Kb tetramer, an FITC-conjugated anti-CD62L antibody (Pharimgen), and a tricolor-labeled anti-CD8 antibody (Caltag) for 30 min on ice (20). Samples were examined by FACS Calibur flow cytometry, and in the analysis CD8+ T cells were selected and the data plotted as tetramer (PE) versus CD62L (FITC), as indicated.

Statistical analysis. Comparisons between experimental groups were made using the two-tailed Student t test. P < 0.05 was considered significant.

RESULTS

Chloroquine improves cross-presentation of soluble OVA to naïve OT-I cells in vitro and in vivo. Freshly isolated splenic DCs are induced to mature through overnight culture in vitro, so that they acquire the capacity to process and present newly encountered antigens (54). Chloroquine and NH4Cl have been shown to inhibit the intravesicular acidification and marked proteolysis that occur in partially and fully mature DCs (1, 22) and also in nonprofessional APCs (i.e., T2 cells deficient in transporter associated with antigen processing) (40). Here, we first assessed the effect of chloroquine treatment on the capacity of splenic DCs to process and present exogenous soluble OVA by using an in vitro proliferation assay of OVA-specific transgenic CD8+ T cells (OT-I cells). The presence of low concentrations of chloroquine, 6.5 μM and 2 μM, throughout the duration of the proliferative assay improved the cross-presentation to naïve T cells (Fig. 1A). Chloroquine treatment did not affect the peptide presentation of splenic DCs loaded with the SIINFEKL peptide (OVA257-264) to CD8+ T cells at these low concentrations. By contrast, the highest dose of chloroquine (20 μM) showed an inhibitory effect on T-cell proliferation in both systems, as cell numbers similar to those of the non-chloroquine-treated cells in the absence of antigen were observed. Thus, chloroquine treatment improved the cross-presentation of antigens in maturing DCs, otherwise susceptible to rapid endosomal protease degradation, sustained by the acidic pH (1).

We then examined the efficiency of cross-presentation of soluble OVA in vivo in the presence of chloroquine. In vivo cross-presentation of a soluble antigen that is not cell associated is more strictly dose related (35). It has been reported that very small amounts of cell-associated OVA are able to stimulate OT-I cells in vivo (29). On the other hand, free soluble OVA is presented much less efficiently than cell-associated OVA to OT-I cells. In our system, CFSE-labeled OT-I cells were transferred into recipient mice treated 1 day later with a single i.v. injection of various concentrations of OVA diluted in PBS and in the presence or absence of chloroquine. The proliferative responses of these cells derived from the lymph nodes were analyzed 3 days after adoptive transfer by flow cytometry (Fig. 1B). An evident in vivo OT-I proliferative
response was seen in the lymphoid organs of mice given 200 μg of OVA, whereas low levels of proliferation were seen in mice given the lowest concentration (2 μg of OVA), independently from the chloroquine treatment. In mice given an intermediate dose (20 μg OVA), those receiving chloroquine during priming showed a higher proliferation of CFSE-labeled OT-I cells than did the untreated mice (P < 0.05), thus confirming the ability of chloroquine treatment to improve cross-presentation of soluble antigens to naïve CD8+ T cells in vivo.

**Chloroquine improves induction of OVA-specific CTLs upon alum-OVA immunization in vivo.** Then we wondered whether chloroquine was capable of improving cross-priming of not only an enriched population of transferred OT-I cells but also naïve OVA-specific cytotoxic T-lymphocyte (CTL) precursors in vivo. It has been previously shown that adjuvants are required for priming CTLs with native OVA and some particulate forms of OVA. In particular, OVA in complete Freund’s adjuvant (27), OVA incorporated into immunostimulating complex adjuvant (21) or into liposomes (10), or OVA adsorbed onto alum and mixed with a saponin surfactant (QS-21) (36) primed CTLs in vivo. There is very little evidence that aluminum adjuvants generate MHC class I cytotoxic T cells (30). Alum alone is a poor inducer of Th1 cellular immune responses and stimulates the production of IgE and IgG1 antibodies in mice, which is consistent with a dominant profile of Th2 lymphocyte immune response (19). Here, we examined if chloroquine treatment could improve the induction of CTLs specific for the immunodominant epitope SIINFEKL, by a single inoculation of mice with alum-OVA. To this end, spleen cells from mice primed with alum-OVA 9 days earlier were cultured with irradiated peptide-loaded syngeneic cells for 5 days and then assayed for cytolytic activity. As shown in Fig. 2A, only mice immunized in the presence of chloroquine generated detectable OVA-specific CTLs, whereas those immunized in the absence of the drug did not (P < 0.01 at the effector/target ratio of 100:1). Although the increase in antigen-specific CTL activity was not substantially high, it was nonetheless relevant, considering the poor induction of CTLs by alum-based adjuvants. We also tested the primed mice for the presence of OVA-specific IgG antibodies: in both treated and untreated groups, the antibody levels were comparable (P > 0.05), and IgG1 was the dominant isotype, independently of the chloroquine treatment (Fig. 2B).

**Chloroquine treatment during priming with alum-OVA improves the induction of memory CD8+ T cells.** It was necessary to determine whether the increased numbers of primed CTLs due to the combination of a single dose of alum-OVA and chloroquine treatment have the capacity to develop effective long-term memory T cells. The magnitude of a secondary immune response correlates with the size of memory T cells induced by the cross-presented antigen during priming (28, 34). To this end, mice were vaccinated with alum-OVA in the presence or absence of chloroquine and 8 weeks later we elicited a recall response by boosting them with WSN/OVA-I virus bearing the T-cell epitope SIINFEKL in the stalk region of the viral neuraminidase (50). Seven days after the boost, we determined the proportion of OVA-specific CD8+ T lymphocytes in the pooled MLN and the spleens that were functional by intracellular IFN-γ staining. Approximately 7.6% and 6.6% of CD8+ T cells in MLN and bulk splenocytes, respectively, of chloroquine-treated mice produced IFN-γ after stimulation with OVA peptide, versus approximately 2.8% and 2.5% of CD8+ T cells from the untreated mice (P < 0.01) (Fig. 3A). Lower levels of antigen-specific CD8+ T cells were found at this time of infection in the unprimed mice. Moreover, lym-
phocytes that were not stimulated with peptide showed back-
ground staining similar to that of the isotype control immuno-
globulin (H11021; data not shown). The higher proportion of
CD8/H11001 T cells in bulk splenocytes of chloroquine-treated mice
that showed as MHC class I-SIINFEKL tetramer positive and
CD62LLo (Fig. 3B) further indicates that priming of mice in
the presence of this drug induces larger CD8/H11001 T-cell memory
responses.

Overall, these results show that concurrent immunization of
mice with alum-OVA and chloroquine treatment supports
higher CD8/H11001 T-cell expansion of primary effectors and thus a
large population of memory CD8/H11001 T cells that undergo a rapid
expansion and recruitment following pulmonary infection with
the recombinant influenza virus.

**Chloroquine improves cross-priming via its effect on DCs.**
To ascertain that the improvement in cross-priming through
chloroquine in vivo was related to chloroquine’s capacity to
increase cross-presentation by DCs, as observed in our studies
in vitro (Fig. 1A), CFSE-labeled transgenic OT-I cells were
transferred into C57BL/6 mice primed 1 day later with OVA-
DCs, which had been treated with chloroquine. In particular,
splenic DCs cultured overnight were pretreated in vitro with
chloroquine or medium alone for 30 min followed by the ad-
dition of 3 mg of soluble OVA or 1/H9262 g of SIINFEKL peptide
for 1 h and extensively washed. After a 2-hour chase, chloro-
quione-treated OVA-DCs were injected into mice, who received
chloroquine s.c. (in order to guarantee a continuous presence
of chloroquine during antigen processing in vivo), whereas the
untreated OVA-DCs were injected into chloroquine-untreated
mice. Three days after priming, recipients were euthanized and
the lymphoid organs were analyzed by flow cytometry. As
shown in Fig. 4, OT-I cells proliferated more in the lymphoid
organs of chloroquine-treated mice than in untreated mice
which had received OVA-DCs (P < 0.05), thus confirming that
chloroquine treatment improves in vivo cross-priming of naïve
CD8/H11001 T cells by maturing DCs. It is improbable that cross-
priming was due to contaminating soluble OVA, because
OVA-DCs were extensively washed and chased before the immunization procedures and because cross-priming by soluble antigens (including OVA) generally requires high antigen concentrations (Fig. 1B) (29). Similar percentages of proliferating OT-I cells induced upon immunization with SIINFEKL-DCs were measured independently of the chloroquine treatment. To further corroborate the finding that chloroquine was capable of improving the primary antigen-specific response of CTL precursors in vivo by boosting the cross-presentation capacity of DCs (Fig. 1A), we tested the additive effect of PMA and chloroquine because the former has already been demonstrated to improve cross-presentation (37, 38) and to function as a nonspecific Rho GTPase activator capable of promoting endocytosis and antigen presentation by murine DCs (47). The presence of OVA-specific CTL effector cells in the spleens was determined on day 9 by 51Cr release assay, after one round of restimulation in vitro in the presence of peptide-loaded syngeneic cells (Fig. 5). Groups of mice injected with SIINFEKL-pulsed DCs were used in these assays to make sure that the chloroquine treatment in vivo did not affect the ability of DCs to present the synthetic peptide. Mice treated with chloroquine and receiving chloroquine-treated OVA-DCs efficiently induced SIINFEKL-specific CTLs, whereas the untreated group of mice did not. Furthermore, the combined use of chloroquine and PMA in vitro and subsequent injection in chloroquine-treated mice determined an additive effect that more closely correlates the functional role of the chloroquine with the reduced antigen proteolysis and enhanced cross-presenta-

OVA-DCs were extensively washed and chased before the immunization procedures and because cross-priming by soluble antigens (including OVA) generally requires high antigen concentrations (Fig. 1B) (29). Similar percentages of proliferating OT-I cells induced upon immunization with SIINFEKL-DCs, in the presence or absence of chloroquine, as described in Materials and Methods. Lymph nodes were analyzed 3 days later. All profiles obtained were gated on CD8+ T cells, and the frequencies of cells that have undergone one or more divisions are indicated (average of n = 6 mice/group; data are represented as means ± standard deviations).

To further corroborate the finding that chloroquine was capable of improving the primary antigen-specific response of CTL precursors in vivo by boosting the cross-presentation capacity of DCs (Fig. 1A), we tested the additive effect of PMA and chloroquine because the former has already been demonstrated to improve cross-presentation (37, 38) and to function as a nonspecific Rho GTPase activator capable of promoting endocytosis and antigen presentation by murine DCs (47). The presence of OVA-specific CTL effector cells in the spleens was determined on day 9 by 51Cr release assay, after one round of restimulation in vitro in the presence of peptide-loaded syngeneic cells (Fig. 5). Groups of mice injected with SIINFEKL-pulsed DCs were used in these assays to make sure that the chloroquine treatment in vivo did not affect the ability of DCs to present the synthetic peptide. Mice treated with chloroquine and receiving chloroquine-treated OVA-DCs efficiently induced SIINFEKL-specific CTLs, whereas the untreated group of mice did not. Furthermore, the combined use of chloroquine and PMA in vitro and subsequent injection in chloroquine-treated mice determined an additive effect that more closely correlates the functional role of the chloroquine with the reduced antigen proteolysis and enhanced cross-presenta-

To investigate whether chloroquine treatment had some effect on cross-priming CD8+ T-cell-mediated responses in vivo, we explored vaccination strategies based on OVA as soluble protein, alum-adsorbed OVA, or OVA pulsed on DCs in C57BL/6 mice. Our data demonstrate that in all these cases, and independently of the presence of adjuvants, concurrent chloroquine treatment improved the priming provided by these immunogens. These results further corroborate the previous
evidence that chloroquine enhanced human CD8<sup>+</sup> T-cell recall responses against viral antigens (1). Here, we used overnight cultured murine splenic DCs, which showed higher cross-presentation of the immunodominant CTL epitope of OVA to OT-I cells in the presence of chloroquine, in both in vitro and in vivo proliferative assays. Although our studies do not provide direct evidence on the mechanisms responsible for an enhanced CD8<sup>+</sup> T-cell response, this effect can probably be explained by the chloroquine-mediated rescue of OVA protein from the endocytic degradation that occurs in maturing DCs, as well as facilitating export of the antigen to the cytosol for proteasome-dependent processing (1).

The additive effect of inducing antigen-specific CTLs in vivo following immunization with OVA-DCs treated with chloroquine combined with PMA further supports this evidence. PMA has been shown to promote antigen presentation of murine DCs through enhanced endocytosis mediated by Rho family GTPases (38, 47). In addition, PMA stimulates a NOX2-mediated production of reactive oxygen species which results in proton consumption in DC phagosomes, reduced antigen degradation, and ultimately improved cross-presentation (43). Thus, it may be speculated that the observed additive effect of chloroquine in conjunction with PMA may be explained by increased cytosolic availability of antigen mediated by a more efficient uptake, reduced endosomal degradation, and facilitated export of the endocytosed soluble OVA to the cytosol. Recent findings highlight several questions concerning the relative contributions of endocytosis and DC subpopulations in determining the ability for cross-presentation (13–15, 44). In this context, Burgdorf et al. (8) described in CD8α<sup>+</sup> DCs a mannose receptor-mediated internalization of soluble OVA into a stable early endosomal compartment for subsequent cross-presentation through a proteasome-dependent mechanism, whereas the constitutively pinocytosed antigen was exclusively transported into lysosomes for MHC II-restricted presentation. Thus, it would be of interest to determine whether chloroquine improves cross-presentation of soluble OVA sampled by receptor-mediated endocytosis, constitutive pinocytosis, or both.

The magnitude of the primary immune response, as well as the extent of memory T-cell populations, is dependent on the dose of antigen used for immunization (28, 34, 35, 53). It has also been demonstrated that the size of the memory T-cell pool is the major determinant for the magnitude of secondary immune responses, in addition to the effective antigen dose during challenge (23, 28, 34). In this study, mice were immunized only with a single dose of antigen, in the presence or absence of chloroquine. Then, we boosted them with WSN/OVA-I virus to fully establish a secondary SIINFEKL-specific T-cell stimulation. By this means, we could clearly show a higher recall response in mice that were primed in the presence of chloroquine. Although our analysis was exclusively focused on numbers and functions of CD8<sup>+</sup> T cells specific to the immunodominant epitope OVA<sub>257–264</sub>, it may be envisioned that these results could also be extended to subdominant epitopes of OVA protein (48).

Chloroquine is known to block MHC class II-dependent antigen processing and presentation by affecting lysosomal acidification and invariant chain dissociation from the MHC class II molecules (42). Continuous treatment with high doses of chloroquine in vivo is an established immunosuppressive therapy for autoimmune diseases (16). In our proliferative assay in vitro, we found an inhibitory effect by using 20 μM, and some concerns may arise about the dosage of chloroquine that we used in our experiments in vivo for priming mice. Indeed, mice treated with the drug did not show any distress or change in animal behavior. The improved CD8<sup>+</sup> T-cell responses observed in all experiments in chloroquine-treated mice provide evidence that both a short course treatment of chloroquine during priming and the rapid clearance of the drug in normal mice (9) may account for the beneficial effects in vivo. This immunization setting implies that chloroquine favorably affects antigen uptake and processing, whereas maintaining high levels of the drug throughout the proliferative and CTL assays in vitro could negatively affect priming and effector function activities (33, 45). It has been reported that OVA-specific CD8<sup>+</sup> T-cell responses are dependent on CD4<sup>+</sup> T cells (4) and that generating stable and functional CD8<sup>+</sup> T-cell memory relies critically on the help of CD4<sup>+</sup> T cells at priming (26, 49). In this context, the improved antigen-specific CD8<sup>+</sup> T-cell response associated with established long-term T-cell memory in chloroquine-treated mice indicates that T-cell helper functions were preserved and effective during immunization. Additionally, the levels of OVA-specific antibodies measured in chloroquine-treated and untreated mice after a single injection of antigen were comparable, as also reported for the antigen-specific antibody response measured in immune healthy individuals boosted with the hepatitis B virus vaccine (1).

In summary, our data provide further evidence that drugs capable of inhibiting endosomal acidification of DCs could improve the cross-presentation of exogenous soluble antigens to specific CD8<sup>+</sup> T cells in vivo. Improving cross-presentation in generating immune responses after prophylactic or immunotherapeutic immunization is of significant interest for the development of optimal vaccination strategies. In this context, our results encourage further studies to evaluate the possible use of drugs combined with a variety of soluble antigens in the attempt to inhibit excessive antigen degradation and thus facilitate the induction of antigen-specific CD8<sup>+</sup> T cells by these immunogens.

ACKNOWLEDGMENTS

We are grateful to Giuliana Verrone and Monica Gabrielli for assistance with the animal experiments and Roberto Gilardi and Sabrina Tocchio for help with the manuscript.
