ON COMMON ROOTS OF RANDOM BERNOULLI POLYNOMIALS

GADY KOZMA AND OFER ZEITOUNI

ABSTRACT. We prove that with high probability, $d + 1$ random Bernoulli polynomials in $d$ variables of degree $n$ ($n \to \infty$) do not possess a common root.

1. INTRODUCTION

We consider in this paper systems of random polynomials in $d$ variables with independent Bernoulli coefficients, and study whether they possess a common root. Specifically, with $\vec{j}_d = (j_1, \ldots, j_d) \in \mathbb{Z}_+$ and $|\vec{j}_d| = \sum j_i$, let $\{\epsilon_{\vec{j}_d}\}$ be a family of i.i.d. Bernoulli, $\pm 1$-valued random variables. Set $x^{\vec{j}_d} = \prod_{i=1}^d x_i^{j_i}$. We call the following polynomial

$$P(x_1, \ldots, x_d) = \sum_{|\vec{j}_d| \leq n} \epsilon_{\vec{j}_d} x^{\vec{j}_d}$$

a random polynomial in $d$ variables and degree $n$. Our main goal in this paper is to prove the following.

**Theorem 1.** Let $P_1, \ldots, P_{d+1}$ be $d + 1$ independent random polynomials in $d$ variables and degree $n$. Let

$$p(n, d) = \Pr(\exists x \in \mathbb{C}^d : P_i(x) = 0, i = 1, \ldots, d + 1)$$

denote the probability that the $P_i$ have a common zero. Then, there exists a constant $c(d) < \infty$ such that, for all $n$ positive integer,

$$p(n, d) \leq c(d)/n.$$  \hspace{1cm} (1)

In particular, with probability approaching 1 as $n \to \infty$, there does not exist a common zero for the polynomials $P_i, \ i = 1, \ldots, d + 1$, an intuitively obvious but otherwise non-trivial fact. We remark that the result would be trivial if the distribution of the coefficients of the polynomials were to have a continuous distribution — in this case the probability would simply be 0, for all $d$ and all $n$. The point about the result is the discreteness of the coefficients, and we chose Bernoulli as the simplest example.

Another simple point to note is that it is important that the distribution has no atom at 0. Indeed, if we were to take Bernoulli variables taking values 0 and 1 (rather than $\pm 1$), then there would be probability $2^{-d-1}$ that $(0, \ldots, 0)$ is a common root: all you need for this event is that the constant coefficient of all $d + 1$ polynomials would be 0, which happens with probability $2^{-d-1}$ independently of $n$.

The structure of the paper is as follows. In the next section we consider the case $d = 1$. In section 3 we break the event of existence of a common zero according to the type of zero, i.e. according to whether the common zero has at least one zero component, whether it satisfies a relation determined by two monomials (a “dunomial”), or whether it satisfies neither condition; we handle the first case by a dimension reduction.
argument and the last by a projectivization argument. The unipolynomal case (and completion of the proof of Theorem 1) are presented in section 4, where a version of Halász’ theorem plays a decisive role.

Convention. Throughout, $C$ denotes a constant independent of $d$ and $n$ that may change from line to line; $c = c(d)$ denote constants that depend only on $d$ but may change from line to line. On the other hand, constants of the form $c_i(d)$ depend on $d$ only and do not change from line to line.

2. THE ONE-DIMENSIONAL CASE

In this section we will treat the one-dimensional case. Recall that all our random polynomials have $\pm 1$ Bernoulli coefficients. We will prove

**Theorem 2.** Let $P_1, P_2$ be two independent random polynomials in 1 variable of degree $n$. Let

$$p(n) = \Pr(\exists x \in \mathbb{C} : P_1(x) = P_2(x) = 0).$$

If $n$ is even then

$$p(n) = \left(\frac{4}{\pi} + o(1)\right) \frac{1}{n}$$

and if $n$ is odd then $p(n) \leq c(d)n^{-3/2}$.

We note that the techniques of the next sections apply to the one-dimensional case unchanged, and could yield an upper bound in theorem 2 of the form $c(d)n^{-1/2}$. However, in the one dimensional case there are a few additional tools that yield a more precise result. As we will see, the techniques allow, in principle, to get an asymptotic series, but we will not go that far in the direction of extra-precise results.

**Proof.** The proof relies on two observations.

- Any solution $\xi$ of $P_1$ must satisfy $\frac{1}{2} < |\xi| < 2$.
- Any solution $\xi$ of $P_1$ must be an algebraic integer.

The first observation is obvious: if $|\xi| \geq 2$ then the highest term $c_n\xi^n$ dominates all the others and the sum cannot be zero, if $|\xi| \leq \frac{1}{2}$ then the lowest term $c_0$ dominates all others. The second observation is by definition: an algebraic integer is defined as a number satisfying a monic polynomial, i.e. a polynomial with integer coefficients and highest coefficient equal to 1. Nevertheless, there is an algebraic fact in the background of the definition, which we will use

*A number is a root of a monic polynomial if and only if it is the root of an irreducible monic polynomial.***

See any standard textbook on algebraic number theory, e.g. [AW04, Page 93]. These two observations allow us to classify all potential solutions of low algebraic order. For example, if $\xi$ is a rational solution then its irreducible polynomial is $x - \xi$ and since it is monic, $\xi$ must be an integer, and by the first observation it must be $\pm 1$. If the irreducible polynomial of $\xi$ is of degree 2, it must be $x^2 - ax - b$. But because it is irreducible, the other solution $\xi'$ is also a solution of $P_1$, so it must also be between $\frac{1}{2}$ and 2. But $a = \xi + \xi'$ and $b = \xi\xi'$ so both are between 4 and $-4$. We get that we only need to examine a finite collection of numbers (naively 98, since $a$ has 7 possibilities, $b$ has 7 possibilities, and each polynomial has two roots — this number can be reduced easily, but this is not important at this step). The same argument gives
Lemma 1. For every $\ell$ there are only finitely many numbers whose irreducible polynomial has degree $\ell$ that can be roots of a polynomial (of arbitrary degree) with coefficients $\pm 1$.

Next let us recall the so-called “sharp inverse Littlewood-Offord theorem” of Tao and Vu [TV10, theorem 1.9], which we now quote almost literally:

Let $A, \delta > 0$ and let $(\xi_1, \ldots, \xi_n)$ be complex numbers such that

$$\Pr\left(\sum_{i=0}^{n} c_i \xi_i = 0\right) \geq n^{-A}.$$  

Then there exist a symmetric generalized arithmetic progression (all of whose elements are distinct) of rank $B \leq 2A$ and volume $\leq C(A, \delta)n^{4A-B/2+C(A)\delta}$ which contains all but $C(A, \delta)n^{1-\delta}$ of the $\xi_i$ (counting multiplicity).

The value of $\delta$ will play no role, so we set it to $\frac{1}{2}$. We apply this theorem with $\xi_i = \xi^i$ and get that if $\Pr(\sum_{i=0}^{n} c_i \xi^i) \geq n^{-A}$ then most $\xi_i$s must be contained in a generalized arithmetic progression of rank $B \leq 2A$. More precisely, there exists some $\gamma_1, \ldots, \gamma_B \in \mathbb{C}$ such that we have $\xi^i = \sum_j n_{i,j} \gamma_j$ with $n_{i,j}$ integers for at least $n - \text{CN}^{1-\delta} = n - C\sqrt{n}$ indices $i$. Therefore, for $n$ sufficiently large, $n > n_0(A, \delta)$, it must hold for some $B + 1$ consecutive $i$s, call them $i, \ldots, i + B$. But these $B + 1$ vectors of coefficients $n_{i,j}$ must be dependent over the rationals $Q$, so $\xi^i, \ldots, \xi^{i+B}$ must be dependent over $Q$, which means that $\xi$ satisfies a polynomial with rational coefficients of degree $\leq B$. In other words we proved

Lemma 2. For all $A > 0$ there exists $n_0(A)$ such that if $n > n_0(A)$ and if $\Pr(\sum_{i=0}^{n} c_i \xi^i = 0) \geq n^{-A}$ then $\xi$ must be of algebraic degree $\leq 2A$.

Let us finish the proof of theorem 2. Using the remarks before lemma 1 we write

$$\Pr(\exists x : P_1(x) = P_2(x) = 0) = \Pr(P_1(1) = P_2(1) = 0)$$
$$+ \Pr(P_1(-1) = P_2(-1) = 0)$$
$$- \Pr(P_1(1) = P_1(-1) = P_2(1) = P_2(-1) = 0)$$
$$+ O(Pr(\exists x of algebraic degree $\in \{2, 3, 4, 5\} : P_1(x) = P_2(x) = 0))$$
$$+ \Pr(\exists x of algebraic degree $> 5 : P_1(x) = P_2(x) = 0))$$
$$= I + II + III + O(IV + V) \tag{2}$$

The estimate of the first three terms is straightforward. The first term $I$ is exactly the probability that a random walk on $\mathbb{Z}$ returns to 0 at time $n$, squared, since we need both $P_1$ and $P_2$ to be zero. This can be estimated by Stirling’s formula and we get

$$I = II = \begin{cases} (\frac{2}{\pi} + o(1)) \frac{1}{n} & \text{n is even} \\ 0 & \text{n is odd.} \end{cases}$$

The third term $III$ is the probability that $P_1$ and $P_2$ both vanish at $\pm 1$. This probability vanishes when $n$ is odd and, when $n$ is even, it equals the probability that both $\sum_{i=0}^{n/2} c_{2i} = 0$ and $\sum_{i=0}^{n/2} c_{2i+1} = 0$; those events are independent, so $|III| \leq Cn^{-2}$ ($III$ is negative).

For the term $IV$ we use lemma 2 with $A = \frac{3}{4}$ and see that any $\xi$ such that $\Pr(\sum c_i \xi^i = 0) > n^{-3/4}$ must be rational, so does not contribute to $IV$. So we get that any $\xi$ with algebraic degree $\in \{2, 3, 4, 5\}$,

$$\Pr(P_1(\xi) = P_2(\xi) = 0) \leq \left(n^{-3/4}\right)^2 = n^{-3/2}.$$
By lemma 1 there are only finitely many ξ which we need to consider, so $IV \leq C n^{-3/2}$.

Finally, for the term $V$ we fix $P_1$. It has (at most) $n$ different roots. For each one we ask what is the probability that it is also a root of $P_2$? We use lemma 2 with $A = 5/2$ and get that, for $n$ sufficiently large, any ξ such that $Pr(P_2(ξ) = 0) \geq n^{-5/2}$ has algebraic degree $\leq 5$ so does not contribute to $V$. So we can write

$$V = Pr(\exists \text{a root of } P_1 \text{ with algebraic degree }> 5 \text{ which is also a root of } P_2)$$

$$\leq n \max \{Pr(P_2(ξ) = 0) : ξ \text{ with algebraic degree }> 5\} \leq n \cdot n^{-5/2} = n^{-3/2}.$$ 

Plugging the estimates for $I–V$ into (2) finishes the proof of theorem 2. □

### 3. Breakup into Cases

The proof of Theorem 1 goes by induction on the number of variables $d$. Before starting it, we introduce some notation and prove auxiliary lemmas.

In the sequel, for a collection of polynomials $Q_1, \ldots, Q_ℓ$, we write $Z(Q_1, \ldots, Q_ℓ)$ for their common zeros, i.e. the algebraic set determined by this collection. This algebraic set may be reducible. We denote $Z_∞(Q_1, \ldots, Q_ℓ)$: The union of all irreducible components of $Z$ with dimension $> 0$. 

(we call this “$Z_∞$” because it contains infinitely many points, if non-empty). For the definition of irreducible components of an algebraic variety, see any standard textbook, e.g. [S74].

Next divide $Z = Z_1 \cup Z_2 \cup Z_3$ (these are not directly related to $Z_∞$ — we hope the reader will not be too confused by the somewhat inconsistent use of the subscript), as follows:

$Z_1(Q_1, \ldots, Q_ℓ)$: The elements $(x_1, \ldots, x_d) \in Z$ which satisfy a monomial, or in other words, that (at least) one of the $x_i$ is zero.

$Z_2(Q_1, \ldots, Q_ℓ)$: The elements $(x_1, \ldots, x_d) \in Z$ which do not satisfy a monomial but do satisfy a dunomial\(^1\) of degree at most $n$, i.e. such that for some $\vec{α} \neq \vec{β}$ with $\sum \alpha_i \leq n, \sum \beta_i \leq n,$

$$\prod_{i=1}^{d} x_1^{α_i} \pm \prod_{i=1}^{d} x_2^{β_i} = 0$$

$Z_3$: The elements of $Z$ which satisfy neither a monomial nor a dunomial.

Applying this to $ℓ$ random polynomials $P_1, \ldots, P_ℓ$ of degree $n$ in $d$ variables we define the following corresponding probabilities

$$p_i(n, d, ℓ) = Pr(Z_i(P_1, \ldots, P_ℓ) \neq \emptyset) \quad i \in \{1, 2, 3, ∞\}$$

We first estimate $p_∞$ — we believe this is the most interesting estimate in the proof (it definitely took us longest to discover).

**Lemma 3.** For any $d \geq 2$ and all $n$ positive integer,

$$p_∞(n, d, ℓ) \leq dp(n, d-1, ℓ).$$

**Proof.** Let ‘$C$’ be an arbitrary irreducible component (of dimension necessarily $≥ 1$) of $Z_∞(P_1, \ldots, P_ℓ)$. We examine ‘$C$’ in the $d$ dimensional projective space $P^d$ i.e. add a $d + 1^{st}$ variable and homogenize by multiplying each monomial $x_1^{α_1} \ldots x_d^{α_d}$ by $x_0^{n − \sum \alpha_i}$ so we get a system of homogeneous polynomials of degree $n$ in $d + 1$ variables. A nice

\(^1\)Binomial might have been a better term, but is already taken in the literature.
feature is that there is no difference between the added variable and the old ones — our polynomials are
\[ \sum_{\tilde{d}_{d+1}\sum_{a_{d} = n}} \epsilon_{\tilde{d}_{d+1}} \prod_{i=1}^{d+1} x_i^{a_i}. \]
Clearly the set of zeros of the homogenized system has a component of dimension \( \geq 2 \) because
\[ \{ (\lambda x_1, \ldots, \lambda x_d, \lambda) : (x_1, \ldots, x_d) \in \mathcal{C}, \lambda \in \mathbb{C} \} \]
are all zeros. Hence the dimension of \( \mathcal{C} \) as a projective variety (denoted now as \( \mathcal{\tilde{C}} \)) is \( \geq 1 \).

We now apply the projective dimension theorem [H77, §1, theorem 7.2] to see that \( \mathcal{\tilde{C}} \) intersects with the plane \( x_1 = 0 \). Call this intersection \((\mu_1, \ldots, \mu_{d+1})\). By definition they cannot be all zero — this is not a legal point in the projective space. So let \( k > 1 \) satisfy that \( \mu_k \neq 0 \), and in this case we may assume \( \mu_k = 1 \) and remove \( \mu_k \) from our equations. We are left with \( d - 1 \) variables: \( \tilde{V} = \{ 2, \ldots, d + 1 \} \setminus \{ k \} \). So we get that a system of \( \ell \) independent polynomials in \( d - 1 \) variables
\[ \sum_{\tilde{d}_{d+1}\sum_{i \leq n}} \epsilon_{\tilde{d}_{d+1}} \prod_{i \in \tilde{E}} x_i^a \]
has a common zero. In other words, if we denote the event that this system of equations has a common zero by \( E_k \), then the conclusion is the event that \( Z_{\infty}(P_1, \ldots, P_{\ell}) \neq \emptyset \) implies \( E_1 \cup \cdots \cup E_d \). By definition each of the \( E_k \) has probability \( p(n, d - 1, \ell) \). We need to count over \( k \), which has \( d \) possibilities, so we get that \( p_{\infty}(n, d, \ell) \leq dp(n, d - 1, \ell). \)

We proceed with estimates of \( p_1 \) for finite \( \ell \). The obvious one is

**Lemma 4.**
\[ p_1(n, d, \ell) \leq dp(n, d - 1, \ell). \]

**Proof.** If \( x_i = 0 \) for some \( i \) we can throw it and all terms containing it and we get exactly \( p(n, d - 1, \ell) \). The term \( d \) comes from counting over the \( i \). \( \square \)

The second easiest one is

**Lemma 5.** For all \( d \geq 1 \) there exists a constant \( c_1 = c_1(d) \) independent of \( n \) such that for all \( n \) positive integer and all \( \ell \),
\[ p_3(n, d, \ell) \leq p_{\infty}(n, d, \ell - 1) + c_1 n^{-d/2}. \]

**Proof.** Examine \( P_1, \ldots, P_{\ell - 1} \). The event that \( Z(P_1, \ldots, P_{\ell - 1}) \) has a component of dimension \( \geq 1 \) we push into the \( p_{\infty} \) term, so we may assume that all components are points. By Bezout’s theorem [H83, T], the cardinality of \( Z(P_1, \ldots, P_{\ell - 1}) \) is at most \( n^{d} \). This of course applies also to \( Z_3 \) which is a subset of \( Z \).

We now add the last polynomial \( P_\ell \). We need to ask, for every \( \tilde{x} \in Z_3(P_1, \ldots, P_{\ell - 1}) \), what is the probability that \( P_\ell(\tilde{x}) = 0 \)? We apply the Sárközy-Szemerédi theorem [SS65] which states that for any fixed \( \xi \in \mathbb{C}^m \) with all \( \xi_j \) different,
\[ \Pr \left( \sum_{i} \epsilon_i \xi_i = 0 \right) \leq cm^{-3/2}. \]

For \( \tilde{x} \in Z_3 \) we know that they satisfy no dunomial, hence the vector
\[ \xi_j = \prod_{i=1}^{d} x_i^{a_i} \]
(which lives in $\mathbb{C}^m$ for $m$ being the number of possible choices of $\vec{f}$, so $m \approx n^d$) has all entries distinct. Hence

$$\Pr \left( \sum_{j} \epsilon_j \prod_{i=1}^{d} x_j^i = 0 \right) \leq cm^{-3/2}$$

Since $m \geq c(d)n^d$ we get that for each $\vec{x} \in Z_3$ we have $\Pr(P_{\vec{f}}(\vec{x}) = 0) \leq c_1 n^{-3d/2}$. Summing over all $\vec{x}$ and using the information gathered from Bezout’s theorem finishes the lemma.

**Remark.** Using lemma 3 and the idea of lemma 5 (with the Sárközy-Szemerédi theorem replaced by Erdős’ theorem [E45]), one can show that a system of $3d-1$ random polynomials in $d$ variables of degree $n$ does not have a common root, with high probability.

(Recall that Erdős’ theorem states that if all $\xi_i$ are non-zero, then $\Pr(\sum_{i=0}^{n} \epsilon_i \xi_i = 0) \leq Cn^{-1/2}$. The other arguments in the paper, and most notably the use of dunomials and the Halász theorem, are needed in order to reduce the number of required polynomials from $3d-1$ to $d+1$.

4. DUNOMIAL ANALYSIS AND PROOF OF THEOREM 1

Lemma 5 gives a handle on analyzing the set $Z(P_1, \ldots, P_{d+1})$, away from the set of points that are zeros of a dunomial, and do not possess zero coordinates. To be able to carry an induction step and provide a proof of Theorem 1, we thus need to consider such points.

Let

$$D(x) = \prod_{i=1}^{d} x_j^{a_i} \pm \prod_{i=1}^{d} x_j^{b_i}$$

be a dunomial of $d$ variables and degree less than or equal to $n$. Define the order of $D$ to be

$$|D| = \sum_{i=1}^{d} |a_i - b_i|$$

For $\vec{x} \in (\mathbb{C} \setminus \{0\})^d$, let

$$r(\vec{x}) = \min(|D| : D(\vec{x}) = 0)$$

i.e. the minimal order among all dunomials satisfying $\vec{x}$, or $\infty$ if none satisfy it. The following lemma is simple but crucial.

**Lemma 6.** There exists a constant $c_2(d)$ so that for any $n$ positive integer and $x \in (\mathbb{C} \setminus \{0\})^d$, the number $R_n(x)$ of dunomials $D$ of degree $\leq n$ satisfied by $x$ has

$$R_n(x) \leq c_2(d) \frac{n^{2d}}{r(x)^d}.$$  

**Proof.** Fix some $\vec{a}$, and assume $\vec{\beta}$ satisfies that $\prod x_j^{a_i} = \pm \prod x_j^{b_i}$. If we have for some $\vec{y}$ that also $\prod x_j^{a_i} = \pm \prod x_j^{b_i}$ then by definition we must have $|\vec{\beta} - \vec{\gamma}| \geq r(x)$. Thus, $R_n(x)$ is bounded by the total number of dunomials of degree $n$ (which is $\leq c(d)n^{2d}$), divided by the minimal number of integer points in a ball of $\ell_1$ radius $r(x)$. Since the latter is bounded by a constant (depending on $d$) multiple of $r(x)^d$, the lemma follows.

**Lemma 7.** For any $d \geq 1$ there exists a constant $c_3(d)$ such that for all $n$, $\ell$ positive integers,

$$p_2(n, d, \ell) \leq d^3 p(n, d-2, \ell-2) + \frac{c_3(d)(\log n)^{(2-d)\ast}}{n} \quad (4)$$
(where for \( d \leq 2 \) we use the convention that \( p(n, d-2, \ell-2) = 0 \) in the overdetermined case \( \ell > d \))

**Proof.** For any dunomial \( D \), consider the zero set \( Z = Z(D, P_1, \ldots, P_{\ell-2}) \). Since we are interested in \( p_2 \), we may assume \( D \) is reduced i.e. no \( x_i \) appears on both sides, and we will make this assumption throughout the proof. There are two events to consider (corresponding to the two term in (4)), one where \( Z \) has components of dimension \( \geq 1 \), and the other where it does not.

Let us start with the case that \( Z \) does have components of dimension \( \geq 1 \). In this case we do not need to know the exact value of the dunomial \( D \) — we only need to know which \( x_i \) appear on the two terms. We now repeat the analysis of lemma 3 namely embed one irreducible component \( C \) of dimension \( \geq 1 \) into the projective space \( \mathbb{P}^d \) and use the projective dimension theorem. This time, however, we do not intersect \( C \) necessarily with \( x_1 = 0 \), but we intersect it with some \( x_i = 0 \) for some \( x_j \) that appears in the dunomial \( D \). The intersection is still non-empty, and of course, if \( x_i = 0 \) and \( D(\tilde{x}) = 0 \) then at least one other \( x_j \) (appearing in the other term of \( D \) i.e. in the term not containing \( x_j \)) must also be zero (here we use that \( D \) is reduced). Now return to the affine setting \( C_0 \) as in lemma 3, i.e. find some \( k \) such that the solution \( \tilde{x} \) has \( x_k \neq 0 \) and set \( x_k = 1 \). Recall that in lemma 3 we defined events \( E_k \) that the system one gets by setting \( x_1 = 0 \) and \( x_k = 1 \) has a common root. Here we need instead events \( E_{i,j,k} \) that the system one gets by setting \( x_i = x_j = 0 \) and \( x_k = 1 \) has a common root. But the conclusion is the same: if for some reduced \( D \) one has that \( Z(D, P_1, \ldots, P_{\ell-2}) \) has a component of dimension \( \geq 1 \) then necessarily one of the \( E_{i,j,k} \) happened, and each one has probability \( p(n, d-2, \ell-2) \). This explains the first term in (4).

Now assume \( Z \) is finite. Since \( D \) is reduced, the order of \( D \) is also its degree, and by Bezout’s theorem \( |Z_2(D, P_1, \ldots, P_{\ell-2})| \leq |D| n^{d-1} \).

Next fix some \( \bar{x} \in Z \). We now apply a strengthening of the Sárközy-Szemerédi theorem due to Halász [Hal]. Let us recall Halász’ theorem. It states that for any \( \xi \in C^m \),

\[
\Pr\left( \sum_j c_j \xi_j = 0 \right) \leq \frac{R}{m^{\frac{5}{2}}},
\]

where \( R \) is the number of couples \( j, k \) (not necessarily different) such that \( \xi_j = \pm \xi_k \). In our case (i.e. when \( \xi = \prod x_i^{d_i} \)), \( R \) is exactly given by lemma 6: \( R \) is \( n^d \) + the number of dunomials satisfied by \( x \) (the \( n^d \) term corresponds to the trivial couples \( j = k \)). Hence \( R \leq cn^2d/\pi(x)^d \) as the \( n^d \) term is always smaller and hence can be incorporated into the constant.

Thus we get, for any point \( \bar{x} \in Z \) with \( r(\bar{x}) = r \),

\[
\Pr(P_{\ell-1}(x) = P_\ell(x) = 0) \leq c(d) \left( \frac{n^{2d}}{r^d} \cdot \frac{1}{n^{\ell d/2}} \right)^2 \leq c(d) \frac{1}{r^{2d} n^d},
\]

Since there are at most \( c(d) r^{d-1} \) reduced forms of dunomials of order \( r \), we conclude that

\[
\Pr(\exists D : |Z(D, P_1, \ldots, P_{\ell-2})| < \infty \text{ and } \exists \bar{x} \in Z : r(\bar{x}) = |D| \text{ and } P_{\ell-1}(\bar{x}) = P_\ell(\bar{x}) = 0) \leq c(d) \sum_{r=1}^{2n} r^{d-1} \cdot \frac{1}{r^{2d} n^d} \leq c(d) \left( \frac{\log n}{n} \right)^d, \quad d = 1
\]

\[
\leq c(d) \left( \frac{\log n}{n} \right)^d, \quad d = \geq 2.
\]

The conclusion follows, since if \( Z_2(P_1, \ldots, P_\ell) \neq \emptyset \), either a \( D \) and an \( x \) as above exist, or a \( D \) exists such that \( |Z(D, P_1, \ldots, P_{\ell-2})| = \infty \). \( \square \)
We can now provide the following.

**Proof of theorem 1.** The proof is by induction on $d$. The case $d = 1$ is done by theorem 2. Recall that $p(n, d, \ell)$ is the probability that a system of $\ell$ random polynomials in $d$ variables of degree $n$ has a common root. We write

\[ p(n, d, d+1) = p_1(n, d, d+1) + p_2(n, d, d+1) + p_3(n, d, d+1) \leq \]

Using lemma 4 to estimate $p_1$, lemma 7 to estimate $p_2$ and lemma 5 to estimate $p_3$,

\[ \leq d p(n, d-1, d+1) + d^3 p(n, d-2, d-1) + \frac{c}{n} + p_{\infty}(n, d, d) + c n^{-d/2} \leq \]

Using lemma 3 to estimate $p_{\infty}$,

\[ \leq d p(n, d-1, d+1) + d^3 p(n, d-2, d-1) + \frac{c}{n} + d p(n, d-1, d) \leq \]

and inductively

\[ \leq \frac{c(d)}{n}. \]

(it is also possible to avoid using theorem 2, and estimating the 1 dimensional case using these tools. This will give $p_2(n, 1, 2) \leq (c \log n)/n$ and $p_3(n, 1, 2) \leq c/\sqrt{n}$, so the overall result will be that $p(n, 1, 2) \leq c/\sqrt{n}$ and the same estimate will pass inductively to all $p(n, d, d+1)$.)

**Acknowledgements.** Lots of people have helped us with the algebraic parts of the proof. Special thanks go to Uri Bader, Amos Nevo, Dmitry Gourevich, Avraham Aizenbud, Steve Gelbart and Sergei Yakovenko. We thank Ron Peled and Zeev Rudnik for interesting discussions (unrelated to the algebraic part). Both authors were supported by their respective Israel Science Foundation grants.
