(Received November 24, 2009)

Summary Vitamin E supplement and pseudorabies virus (PRV) infection have a reciprocal role in influencing the maternal immune response, a key determinant of the success or failure of pregnancy. However, it remains unknown whether vitamin E supplement provides protection against PRV-induced failure of pregnancy. This study was therefore conducted to investigate the effect of dietary vitamin E level (0, 75, 375, 750 and 1,500 mg/kg) on the reproduction performance, immunity and expression of Toll-like receptors (TLRs) of PRV-challenged mice. The mortality and abortion rate of PRV-challenged mice decreased with the increase in vitamin E consumption. Overall, PBS-injected mice had a higher live embryo number and live litter size than PRV-challenged mice. Both live embryo number and live litter size of PRV-challenged mice increased with increasing vitamin E levels. Vitamin E supplement resulted in decreased concentration of serum IL-2 and IFN-γ, but increased concentration of serum IL-10. The concentration of serum IgG, IgA and IgM increased with increasing vitamin E levels. In the uterine and embryo mRNA abundance of TLR3, TLR7 and TLR9 was higher in PRV-challenged mice than that in PBS-injected mice fed on the same dosage of vitamin E. The mRNA abundance of embryonic TLR3, TLR7 and TLR9 in PRV-challenged mice decreased with increasing vitamin E levels. Collectively, vitamin E supplement may improve reproductive performance of PRV-challenged mice by attenuating PRV-induced negative effects on the cytokine profile, immunoglobulin synthesis and TLR expression.

Key Words vitamin E, pseudorabies virus, Toll-like receptors, cytokines, immunoglobulins

During pregnancy, the balance of T-helper type-1 (Th1) (cell-mediated immunity) and Th2 (humoral immunity) cytokines is characterized by an initial prevalence of Th2 cytokines, followed by a progressive shift toward Th1 predominance late in gestation (1). Th1/Th2 cytokines play an important role in regulating tolerance to conceptus and supporting pregnancy success. Disturbing the balance of Th1/Th2 has been implicated in infertility, implantation of the embryo, development of the placenta and survival of the fetus (2, 3). Th1 cytokines such as interleukin (IL)-2 and interferon-gamma (IFN-γ) mainly participate in cell immunity and are thought to threaten the maintenance of pregnancy (4). Th2 cytokines such as IL-10 mainly participate in humoral immunity and are considered beneficial for pregnancy and fetal survival (5). Further studies reveal that Th1 and Th2 cytokines are involved in modulating the expression of Toll-like receptors (TLR) such as TLR3 (6) and subsequent production of immunoglobulin (Ig) i.e. IgA, IgM and IgG (7). The factors that can alter the Th1/Th2 balance may affect embryo survival and pregnancy success (8, 9). Therefore, maintaining the Th1/Th2 balance is essential for successful pregnancy.

Vitamin E is a family of tocopherols and tocotrienols, and is one of the essential nutrients for immunity (10) and reproduction (11). Vitamin E is directly involved in pregnancy establishment, and indispensable for the proliferation and/or function of the placenta (12). Growing evidence has indicated that vitamin E supplements can reduce the damage caused by oxidative stress as well as maintaining the integrity of the endometrium (13) and supporting pregnancy (11). In addition, vitamin E supplements can modify Th1/Th2 balance, which could contribute to improved T cell proliferation and increased Th1/Th2 ratio as observed in aged mice (14). Vitamin E is also capable of increasing production of both IFN-γ and IL-2 in aged mice after an influenza infection (15), in colorectal cancer patients (16), retroviral infections (17) and coxsackievirus B3 infection in mice (18). Therefore, it is hypothesized that appropriate vitamin E intake is crucial for maternal immunity and successful pregnancy.

The pseudorabies virus (PRV) is an alphaherpesvirus.
that causes abortion or birth of dead or weak pups in sows (19) and decreased weight of progeny at weaning in mice (20). PRV infection is highly lethal and may represent a sanitary risk for the international trade in porcine embryos because of its origin from blood or semen (19). An immunity-related study indicates that PRV-infected mice have increased synthesis of Th1 inflammatory cytokines (21). Increased Th1 cytokines diminish Th2-mediated immune responses (22), but up-regulate the TLR signaling and thus cause a deleterious hyper-inflammatory state (6), which may account for the failure of pregnancy in PRV-infected mammalians.

Based on the reciprocal role of vitamin E supplement and PRV challenge on the maternal immune response. This study was conducted to determine whether vitamin E supplement could improve reproductive performance in PRV-challenged mice, by attenuating the PRV-induced negative effect on pregnancy with regard to cytokine profile, immunoglobulins synthesis and TLR expression.

**MATERIALS AND METHODS**

*Mice, diets and experimental design.* One hundred and thirty 6-wk-old female Kunming mice (specified-pathogens free) with a mean body weight of 23.2 ± 2.2 g were purchased from Sichuan Academy of Medical Sciences-Sichuan Provincial People’s Hospital Experimental Animal Research Institute [License: SCXK (Chuan) 2004-15]. Mice were housed in cages at 20–25˚C, relative humidity of 55–65% and 12 h light/dark cycle throughout the study in a small animal laboratory of Animal Nutrition Institute, Sichuan Agricultural University. The protocol of this study was approved by the Animal Care and Use Committee of Animal Nutrition Institute, Sichuan Agricultural University and was carried out in accordance with the National Research Council’s Guide for the Care and Use of Laboratory Animals.

Vitamin E-deficient basal diet was formulated based on AIN-93G (Table 1). Twenty mice were fed on the control diet (containing vitamin E at 75 mg/kg) and the others were fed on a vitamin E-deficient diet to establish a vitamin E deficiency model. After 7 wk. venous blood was collected once every 7 d intra-orbitally from eye sockets. Alpha-tocopherol concentration was determined with high performance liquid chromatography (HPLC). Compared to the control group, the plasma vitamin E concentration of mice fed on the deficient diet significantly decreased (less than 0.5 μg/mL) with no typical symptoms of vitamin E deficiency for 7 wk. This was considered as the successful establishment of vitamin E deficiency model (23). Eighty-nine mice weighing 41.8 ± 6.5 g were divided into five groups (n = 16–20 per group) and fed on treatment diets containing different vitamin E levels (0, 75, 375, 750, 1,500 mg/kg, dl-α-tocopherol acetate. Sigma, T3376. HPLC≥96%). After 3 wk of adaptation, 4 female mice per cage were housed overnight with 2 male Kunming mice. Pregnancy was determined the next morning by the presence of a vaginal plug and this was designated as gestational day 0.5.

After confirmation of pregnancy, female mice were intraperitoneally injected with 0.5 mL of PRV solution to offer PRV at 3.5 × 10^3 PFU/g BW. This PRV injection dosage was determined in a preliminary trial and this dosage would affect the brain functions and reproductive functions without being lethal to the injected mice (data is not shown). The control group was intraperitoneally injected with 0.5 mL of phosphate buffered saline (PBS). PRV or PBS-injected mice were housed separately in temperature-controlled and well ventilated rooms under a 12-h light/dark cycle. All the mice were daily supplied with fresh diets refrigerated at 4˚C and had free access to water at all times.

**Blood sampling and tissue collection.** On day 9 of gestation, ten mice per group were fasted for 12 h. blood was collected via intra-orbital bleeding under aerrane asphyxiation and the data for the collected samples were recorded. Samples for the left eye were collected samples were recorded. Samples for the left eye were collected. Alpha-tocopherol concentration was determined with high performance liquid chromatography (HPLC). Compared to the control group, the plasma vitamin E concentration of mice fed on the deficient diet significantly decreased (less than 0.5 μg/mL) with no typical symptoms of vitamin E deficiency for 7 wk. This was considered as the successful establishment of vitamin E deficiency model (23). Eighty-nine mice weighing 41.8 ± 6.5 g were divided into five groups (n = 16–20 per group) and fed on treatment diets containing different vitamin E levels (0, 75, 375, 750, 1,500 mg/kg, dl-α-tocopherol acetate. Sigma, T3376. HPLC≥96%). After 3 wk of adaptation, 4 female mice per cage were housed overnight with 2 male Kunming mice. Pregnancy was determined the next morning by the presence of a vaginal plug and this was designated as gestational day 0.5.

**Blood sampling and tissue collection.** On day 9 of gestation, ten mice per group were fasted for 12 h. blood was collected via intra-orbital bleeding under aerrane asphyxiation and centrifuged at 3,000 rpm for 15 min. Serum samples were separated and stored at −80˚C until analysis. Brain, liver, uterus and live embryos were collected after CO2 asphyxiation and the data for the collected samples were recorded. Samples for the left and right sides of the uterus and embryos were collected individually. All samples were immediately frozen in liquid nitrogen and stored at −80˚C until analyzed.

**Mortality and abortion rate.** After PRV injection, the number of dead mice and non-pregnant mice in each group was recorded for the calculation of mortality and abortion rate. Abortion number included pregnant (plug-positive) females that yielded no pups and mice miscarried on day 9 of gestation. “Successful” pregnancies were those yielding at least one pup (24). Live litter size of each mouse was recorded within 12 h post parturition.

**PRV detection.** PCR for detection of viral DNA was

1 Provided per kg of diet: Ca 5,000 mg; P 1,561 mg; K 3,600 mg; Na 1,019 mg; Cl 1,517 mg; Mg 510 mg; Fe 35 mg; Zn 30 mg; Mn 10 mg; Cu 6 mg; I 0.2 mg; Se 0.15 mg. Antioxidant (TBH) 20 mg.
2 Provided per kg of diet: VA 4,000 IU; VD 1,000 IU; VK 0.75 mg; VB₆ 6.0 mg; VB₇ 7.0 mg; VB₈ 6.0 mg; VB₁₂ 0.02 mg; nicotinic acid 30.0 mg; d-calcium pantothenate 15.3 mg; folic acid 2.0 mg; biotin 0.2 mg.
PCR reaction was performed in a 10 μL reaction volume containing 5 μL Taq polymerase buffer, 1.6 μL dNTP, 0.2 μL of each primer (10 μM), and 2 μL of extracted cDNA. Cycling conditions were as follows: initial denaturation for 5 min at 95˚C followed by 30 cycles of denaturation for 1 min at 95˚C, annealing for 1 min at 62˚C, extension at 72˚C for 1 min followed by a final extension for 5 min at 95˚C. The RT reaction was performed at 37˚C for 15 min and 85˚C for 5 s.

Real-Time PCR was performed to analyze TLR3, TLR7 and TLR9 mRNA expression in the uterus and embryos using SYBR Green PCR Mix (TaKaRa, Japan). A total volume of 10 μL reaction system contained 5 μL SYBR Premix Ex Taq (2×), 0.2 μL of each primer (10 μM), 1 μL cDNA and 3.6 μL ddH2O. The primer sequences of TLR3, TLR7, TLR9 and β-actin are shown in Table 2.

The PCR reaction was performed as follows: pre-denaturation at 95˚C for 1 min, followed by 40 cycles of denaturation at 95˚C for 5 s, annealing at 60˚C for 30 s, and extension at 72˚C for 30 s. Melt curve conditions were 95˚C for 0 s, 50˚C for 30 s and 95˚C for 0 s (temperature change velocity: 0.5˚C/s). Real-time PCR analysis was performed on cDNA samples using Quantitect Opticon System. The comparative threshold cycle method was used to quantify the relative levels of gene expression and was normalized to the housekeeping gene β-actin. The experiment was repeated three times.

Statistical analysis. Data, except for those presented as percentages, were analyzed by using the one-way ANOVA procedures of the SAS statistical package (V8.1, SAS Institute Inc., Cary, NC). Multiple comparison by Duncan analysis was performed to determine statistical differences between groups. A paired t test was performed to determine differences in hepatic α-tocopherol concentration, serum immunoglobulin and cytokine concentrations, TLR mRNA levels, live embryo number and live litter size between the PBS group and the PRV group fed the same dosage of vitamin E. Results were considered significant at p<0.05 for all tests and data represent the mean±SD of all repeats. Regression anal-
ysis was applied between vitamin E levels ($x \times 10^3$ IU/kg) and live embryo number ($y$) on the 9th day of pregnancy. Survival and miscarriage rates were analyzed by the chi-square test.

**RESULTS**

**PCR confirmation of PRV infection in the brain tissue on the 9th day post-infection**

After PRV or PBS intraperitoneal injection, the virus could be detected in the brain tissue due to the brain-specific location of this virus. PRV was able to be detected on the 9th day post-infection in the brain of mice challenged with PRV, whereas no PRV was present in the PBS-treated mice (Fig. 1).

**Vitamin E supplements enhanced serum, hepatic and uterine α-tocopherol concentration**

Effects of dietary vitamin E level on blood, hepatic and uterine α-tocopherol concentrations of PRV-challenged mice and PBS-treated mice on the 9th day of pregnancy:

infected mice or PBS-treated mice are shown in Tables 3, 4 and 5. The concentration of α-tocopherol increased with increasing vitamin E levels in the diet. Compared to the control groups fed on the same vitamin E dosage, PRV-infected mice had a lower (p<0.05) α-tocopherol concentration in serum, liver and uterus, suggesting that vitamin E requirement should be increased for the function of immune system against PRV infection in pregnant mice.

Vitamin E supplements improved reproductive performance

Vitamin E supplements resulted in a tendency to decrease mortality and abortion rates in PRV-challenged mice (Table 6). For example, the mortality and abortion rate in the vitamin E deficient (0 mg/kg) PRV group was about 5 to 8 times that observed in the 1,500 mg/kg PRV group, indicating the positive effect of high level of dietary vitamin E on disease resistance against PRV infection in pregnant mice.

The lowest live litter size and live embryo number on the 9th day of pregnancy were observed in PRV-challenged mice fed on the vitamin E deficient diet (0 mg/kg) (Table 7). Both live embryo number and live litter

Vitamin E supplements influenced serum cytokine secretion

In PRV-challenged mice, vitamin E supplement resulted in decreased (p<0.05) concentrations of serum IFN-γ and IL-2 (Table 9). In PBS-treated mice, serum IL-2 concentration was also decreased (p<0.05) by vitamin E supplement. In contrast, concentration of serum IL-10 in PRV-challenged mice increased with vitamin E supplements with the highest concentration observed in 375 mg/kg group. Concentrations of serum IL-2 and IFN-γ in mice fed on vitamin E at 75 mg/kg diet was higher (p<0.05) in the PRV group than in the PBS group, but there was no difference (p>0.05) between the PRV group and the PBS group fed vitamin E at 375 mg/kg diet. These results indicate the significance of vitamin E supplements in attenuating Th1 cytokine synthesis but promoting Th2 cytokine synthe-

1,2 Data are presented as means±SD. Means in the same row with no common superscripts differ significantly (p<0.05) among PRV groups.

A paired t test was performed to determine differences in serum cytokine concentration between the PBS group and the PRV group fed on the same dosage of vitamin E. Paired t-test p value represented the difference of means within the same column: p<0.05 was considered significant.

Effects of vitamin E on serum immunoglobulins

Serum IgG, IgA and IgM concentrations in PBS and PRV groups are shown in Table 8. Mice receiving vitamin E at 375 mg/kg diet had the highest serum IgA and IgM concentrations in both PBS and PRV groups. There was no difference for serum immunoglobulins concentrations between PBS groups and PRV groups fed on the same vitamin E level with the exception of IgM in the 375 mg/kg group. For the PRV-challenged mice, the highest serum IgG concentration was observed in the 750 mg/kg group. In contrast, vitamin E supplement did not affect (p>0.05) the serum IgG concentration in the control mice (PBS-injected).

Vitamin E supplements influenced serum cytokine secretion

In PRV-challenged mice, vitamin E supplement resulted in decreased (p<0.05) concentrations of serum IFN-γ and IL-2 (Table 9). In PBS-treated mice, serum IL-2 concentration was also decreased (p<0.05) by vitamin E supplement. In contrast, concentration of serum IL-10 in PRV-challenged mice increased with vitamin E supplements with the highest concentration observed in 375 mg/kg group. Concentrations of serum IL-2 and IFN-γ in mice fed on vitamin E at 75 mg/kg diet was higher (p<0.05) in the PRV group than in the PBS group, but there was no difference (p>0.05) between the PRV group and the PBS group fed vitamin E at 375 mg/kg diet. These results indicate the significance of vitamin E supplements in attenuating Th1 cytokine synthesis but promoting Th2 cytokine synthesis.
Vitamin E Protects PRV-Induced Harm to Reproductive Performance

**DISCUSSION**

In the present study, serum, hepatic and uterine α-tocopherol concentration either in PBS- or PRV-injected mice increased with increasing levels of dietary vitamin E. However, higher improvement was observed in PBS groups rather than PRV groups. For example, supplementation of vitamin E to the diet at 75 mg/kg resulted in two-fold change of the concentration of hepatic α-tocopherol in the PRV-challenged mice, whereas five-fold change of the concentration of hepatic α-tocopherol in the PBS groups was observed when vitamin E was supplemented at a dose of 75 mg/kg to the diet. The relatively lower response of serum, hepatic and uterine α-tocopherol content in PRV-injected mice may imply the negative effect of PRV challenge on vitamin E utilization of pregnant mice. Decreased α-tocopherol concentration was also observed under disease conditions in previous studies (29, 30). These results suggest that dietary vitamin E supplement may attenuate PRV-induced negative effects. This concept is further supported by the decreased embryonic mortality in pregnant mice fed on high levels of dietary vitamin E. The death time, 3–7 d after PRV challenge, was the key phase of embryo implantation. In early pregnancy, the immune function was decreased for successful implantation, but it was not beneficial for protecting against viral infections. Vitamin E deficiency also decreased the immune function of animals (31) and thus resulted in an increased sensitivity to viral infections (32). Previous evidence has demonstrated that vitamin E storage in animals decreases when the animal is exposed to a pathologic state (29, 30). In this study, the α-tocopherol

sis of PRV-challenged mice.

**TLR3, TLR7 and TLR9 expression in uteri and embryos**

Relative expression of TLR3, TLR7 and TLR9 in the uterus and embryos is shown in Fig. 2–4. The mRNA abundance of TLR3, TLR7 and TLR9 in the uterus and embryos of PRV-challenged mice was higher (p<0.05) than that of PBS-treated mice fed on the same vitamin E level, indicating that PRV challenge promotes TLR expression. In contrast, vitamin E supplementation resulted in decreased (p<0.05) mRNA abundance of TLR3, TLR7 and TLR9 in the uterus of PRV-challenged mice, suggesting that the attenuation effect of vitamin E supplementation on PRV-induced TLR expression. Interestingly, PRV-challenged mice with dietary vitamin E supplementation at 75–375 mg/kg had a higher mRNA abundance of TLR3, TLR7 and TLR9 in embryos than those fed a vitamin E deficient diet.

See Fig. 3. Relative mRNA abundance of TLR7 in the uterus (A) and embryos (B) of PBS-injected mice compared with that of PRV-injected mice receiving the same or different vitamin E dosage. The mRNA abundance, measured by Real-time RT-PCR, is expressed relative to β-actin. Data are the mean±SD. Different small letters denote statistical differences (p<0.05) among PRV groups. Asterisk (*) denotes statistical differences (p<0.05) between PRV groups and PBS groups fed on the same vitamin E level according to the paired t test analytical results.

See Fig. 4. Relative mRNA abundance of TLR9 in the uterus (A) and embryos (B) of PBS-injected mice compared with that of PRV-injected mice receiving the same or different vitamin E dosage. The mRNA abundance, measured by Real-time RT-PCR, is expressed relative to β-actin. Data are the mean±SD. Different small letters denote statistical differences (p<0.05) among PRV groups. Asterisk (*) denotes statistical differences (p<0.05) between PRV groups and PBS groups fed on the same vitamin E level according to the paired t test analytical results.
concentration in serum, liver and uterus increased with increasing vitamin E levels. The α-tocopherol transfer protein (α-TTP) is a critical regulator of vitamin E status that stimulates the movement of vitamin E in different tissues (33). Alpha-TTP is expressed in the uterus and α-TTP null mice have a systemic α-tocopherol deficiency (34). As a result, the embryos in the uteri of α-TTP−/− mutants showed developmental failure from 10.5 d postcoitum (35). Higher level of α-tocopherol may promote the transport of α-tocopherol to the uterus and placenta during embryogenesis, which may compensate for vitamin E loss caused by infections. A previous study also reported that high-level vitamin E supplementation in infected mice could reverse immune function disorders caused by retrovirus infection as well as promoting recovery of infected mice (36). It was reported that vitamin E supplementation increased the survival rate of mice infected with type I Diplococcus lanceolatus from 15 to 70% (37).

The oxidative stress in the female genital duct has been implicated in infertility and can cause endometriosis, abortions, acelahalocysts racemosa and implantation failures (38). Vitamin E is one of the natural antioxidants that have been shown to reduce damage caused by oxidative stress as well as maintaining the integrity of the endometrium (13). Vitamin E is directly involved in pregnancy establishment. Jishage et al. demonstrated that α-tocopherol was indispensable for the proliferation and/or function of the placenta but not necessary for the development of the embryo itself (12).

In the present study, increased live embryo number on the 9th day of pregnancy and enhanced live litter size were observed with the increasing of dietary vitamin E levels. It was also found that the live embryo number was lower in PRV-challenged mice than in PBS-treated mice when fed on vitamin E at 75 mg/kg diet, but the live embryo number didn’t differ between PRV-challenged and PBS-treated mice when fed on vitamin E at 375 mg/kg diet. It was inferred that a higher amount of vitamin E may be required by PRV-challenged mice to maintain normal reproductive performance, which is in agreement with previous reports in swine (39) and cows (40).

Generally, factors elevating the Th1/Th2 ratio may cause early embryo loss (8, 9). In contrast, a bias of the Th1/Th2 balance towards Th2 direction has been implicated in successful pregnancy in rodents. The observation that PRV-challenge induced Th1 cytokine (including IL-2 and IFN-γ) synthesis was consistent with previous reports (8, 9, 21). As expected, vitamin E supplement indicated an attenuation effect on PRV infection-caused decrease in live embryo number and live litter size. One possible explanation was that vitamin E supplementation could alter expression of genes associated with the cell cycle and the Th1/Th2 balance (14). In support of this view, compared with PRV-challenged mice fed on vitamin E deficiency diet, mice fed on vitamin E at 375 mg/kg diet had a lower IFN-γ and higher IF-10 concentrations. It was also reported that vitamin E supplementation reduced the risk of acquiring upper respiratory infection in the elderly (41) and influenza infection in aged mice (15). In addition, Th1/Th2 balance may be regulated by sex hormones. Progesterone promoted Th2 cytokine synthesis and inhibited Th1 cytokine synthesis (42). The increased progesterone secretion after vitamin E supplementation (43) may in part account for the increased live embryos and live litter size. In contrast, the observation that oral administration of pharmacological doses of vitamin E (104–198 mg/kg-BW-d) reduced reproductive fitness and impaired the ovarian functions of female mice (44) may provide another explanation for the decreased live embryo number and live litter size caused by excessive amount of vitamin E supplement.

Serum immunoglobulin concentration reflects the level of humoral immunity in animals. During pregnancy, humoral immunity plays an important role in the protection against viral infections. In this study, serum immunoglobulin concentration increased with increasing dietary vitamin E levels from 0 to 375 mg/kg. Previous studies demonstrated that vitamin E could elevate the primary response in lambs to parainfluenza virus infection (45) as well as increasing passive transport of immunoglobulins in influenza virus-infected mice (46). High immunoglobulin level could result in decreased virus load in the tissue of pregnant mice (47). Meanwhile, repeated intravenous injection of immunoglobulins to post-abortion women infected by dermatitis glandularis erythematosa improved antibody and normal pregnancy results (48). Vitamin E deficiency increased virulence of coxsackievirus b3 in mice due to the phenotype change seen in the CVB3/0 virus (from avirulent to virulent) (18). The most likely explanation is host oxidative stress, which is imposed by the lack of vitamin E in the diet. This allows accelerated viral replication, which can lead to an increased opportunity for mutations to occur (18). Thus, proper nutrition (vitamin E) aids the host in withstanding and responding to viral infection and may also decrease the opportunity for pathogens to enhance their virulence by mutation.

Pregnancy is a unique immunological challenge in which an antigenically distinct fetus and placenta develop in the uterus of the mother (2). Rapid innate immune defense against infection usually involves the recognition of invading pathogens by specific pattern recognition receptors, which have been recently attributed to the TLR family (49). The results indicated that TLR3, TLR7 and TLR9 were all expressed both in the uterus and in the embryos of mice on the 9th day of pregnancy following either PRV or PBS injection. This finding is consistent with the results of a previous study (50). Between mice fed on the same dosage of vitamin E, PRV-challenged mice showed higher expression of TLR3, TLR7 and/or TLR9 in the uterus and embryo than PBS-injected mice, indicating the significant role of PRV-invasion in inactivating TLR signaling. In the uterus, TLR3, TLR7 and/or TLR9 expression decreased with increasing dietary vitamin E levels, which was similar to Th1 cytokines secretion. This suggests that the appropriate level of vitamin E supplementation may...
down-regulate the expression of TLR3, TLR7 and TLR9, attenuate inflammatory responses and promote pregnancy success of PRV-infected mice. Previous studies indicate that TLR3 participates in polyinosinic-polycytidylic acid (poly I:C)-induced embryo reabsorption by activation of NK cells infiltrated at the fetal-maternal interface (7). Poly I:C (TLR3 agonist) treatment increased fetal losses to 40.2±1.7% at midgestation stage compared with control CBA×DBA/2 mice (51). Expression level of TLR3 and TLR9 in endometrial tissues varied in a similar pattern during the menstrual cycle. The levels were high in the perimenstrual period and low in the periovulatory period, which implies that differential spatio-temporal expression patterns of TLRs subserve proper innate immunity of the endometrium (49, 52). Overexpression of TLR may be the reason for the highest abortion rates and the lowest live embryo number and live litter size in vitamin E-deficient mice.

Interestingly, the present study showed that vitamin E had different influences on TLR expression in embryos and uteri. Because there is a low placental transfer of tocopherol from the maternal blood to the developing fetus (39), the influence of vitamin E in embryos may differ from that in uteri. TLR3–9 expression changes throughout the embryonic development, which suggests an important role of TLRs in the embryonic development in Drosophila Tolls (53). PRV challenge may increase the requirement of vitamin E by the maternal immune system, and thus decrease transfer of α-tocopherol to the developing fetus.

Conclusively, this study provided the first evidence that PRV challenge resulted in increased vitamin E requirement by pregnant mice. Appropriate vitamin E supplement may improve reproductive performance of PRV-challenged pregnant mice via regulating TLR expression and cytokine synthesis and affecting the concentration of immunoglobulins which are beneficial for the embryonic development and resistance to viral infections.
