Randomized Comparison of the Efficacies and Tolerabilities of Three Artemisinin-Based Combination Treatments for Children with Acute \textit{Plasmodium falciparum} Malaria in the Democratic Republic of the Congo

M. A. Onyamboko,a,c C. I. Fanello,a,b K. Wongsawen,d J. Tarning,a,b P. Y. Cheah,a,b K. A. Tshefu,c A. M. Dondorp,a,b F. Nosten,b,d N. J. White,a,b N. P. J. Daya,b

The Democratic Republic of the Congo (DRC) is one of the five countries with the greatest malaria burden in the world (1). The current national policy for the treatment of uncomplicated \textit{Plasmodium falciparum} malaria consists of amodiaquine-artesunate (AA) or artemether-lumefantrine (AL), although artemether-lumefantrine, which was introduced in 2010, has very limited availability in the public sector. Amodiaquine-artesunate remains the most widely distributed antimalarial therapy in DRC. It was introduced in 2006, replacing sulfadoxine-pyrimethamine, which is now used only as an intermittent preventive treatment in pregnancy. The distribution and access of antimalarials in the rural areas of the country are organized through the public sector, whereas in the urban setting the private sector is predominant. Due to the civil unrest that has affected the country for many years, there is a paucity of data concerning the efficacy of antimalarial drugs in DRC. Available studies show substantial geographic variation in therapeutic efficacy, with similar variation in the prevalence of polymorphic alleles in \textit{P. falciparum} genes associated with parasitological failure (2–4). This reflects the vast geographical area of the country.

Dihydroartemisinin-piperaquine (DP) is an artemisinin-based combination therapy (ACT) with a good safety and tolerability profile which is as effective as other ACTs in areas of endemicity in Asia and Africa (5). Piperaquine is a bisquinoline with a chemical structure similar to those of chloroquine and amodiaquine. The long terminal elimination half-life (>23 days) provides lengthy posttreatment chemoprophylaxis, and the simple once-daily dos-age regimen facilitates adherence (6). Dihydroartemisinin-piperaquine efficacy in Africa has so far been good, although no data are available for DRC.

The aim of this trial was to assess the efficacy of amodiaquine-artesunate for the treatment of uncomplicated \textit{P. falciparum} malaria in children in Kinshasa, DRC, 5 years after its introduction as a first-line treatment, and to compare this with the efficacies of potential alternatives, dihydroartemisinin-piperaquine and artemether-lumefantrine, the latter recently added to the first-line treatment policy. The study was registered with the International Standard Randomized Controlled Trial Number Register ([www.isrctn.org](http://www.isrctn.org)) under registration no. ISRCTN20984426.

MATERIALS AND METHODS

Study area. The study was carried out in a research center located in an urban district of Kinshasa (DRC). Malaria transmission in the area is intense and perennial, with two annual peaks corresponding to the rainy seasons.
Patient population. Patients attending the health center with suspected clinical malaria were screened and enrolled in the study if they met the following inclusion criteria: age 3 to 59 months, weight of ≥5 kg, monoinfection with *Plasmodium falciparum*, parasitemia density between 2,000 and 200,000 asexual parasites/μL, axillary body temperature of ≥37.5°C or history of fever in the preceding 24 h, hemoglobin level of ≥5.0 g/dL, and ability to take oral medication. Patients with severe malaria (7), mixed-species malarial infection, any other significant concomitant illness, underlying disease, malnutrition, known allergy to any of the study drugs, or a clear history of adequate antimalarial treatment with drugs in the previous 72 h or who were taking prophylaxis with drugs having antimalarial activity were excluded. All cases excluded from the trial were referred to the hospital for diagnosis and treatment.

Trial design. This was an individually randomized, open-label study, comparing three fixed-dose oral artemisinin-based combination therapies: dihydroartemisinin-piperaquine (DP), artemether-lumefantrine (AL) and amodiaquine-artesunate (AA).

Treatment. Patients were randomly allocated to receive one of the three study treatments.

AA (artesunate-amodiaquine; Winthrop Sanofi, Kenya) was administered once a day for 3 days according to body weight at a mean dosage of 3.8 mg/kg of body weight/day of artesunate and 10.2 mg/kg/day of amodiaquine. Three types of fixed-dose tablets were used, containing artesunate at 25 mg, 50 mg, or 100 mg plus amodiaquine at 67.5 mg, 135 mg, or 270 mg. Tablets were administered according to the manufacturer’s instructions: 4.5 to 8.9 kg of weight, 1 tablet of 25 mg artesunate/67.5 mg amodiaquine; 9 to 17.9 kg, 1 tablet of 50 mg artesunate/135 mg amodiaquine; and 18 to 35.9 kg, 2 tablets of 100 mg artesunate/270 mg amodiaquine.

DP (Dartep; Guilin Pharmaceutical China; 40 mg dihydroartemisinin and 320 mg piperaquine, each tablet) was administered once a day for 3 days according to body weight with the following scheme: 5 to 7.9 kg, 0.5 tablet; 8 to 9.9 kg, 0.75 tablet; 10 to 14.9 kg, 1 tablet; 15 to 20.9 kg, 1.5 tablets; and 21 to 29.9 kg, 2.0 tablets. This dosage scheme was different from the one recommended by the manufacturer (5 to 10 kg, 0.5 tablet; 11 to 20 kg, 1 tablet; and 21 to 35 kg, 2.0 tablets). We used 5 intervals of weight instead of 3 to improve the therapeutic dose of dihydroartemisinin at the upper limit of the range for each interval. The mean dosage was 3.3 mg/kg/day of dihydroartemisinin and 26.6 mg/kg/day of piperaquine.

AL (Coartem; Novartis, Switzerland) was administered in 6 doses over 3 days (0, 8, 24, 36, 48, and 60 h). Each tablet contained 20 mg artemether and 120 mg lumefantrine, and the mean dose was 2.0 mg/kg of artemether and 12.7 mg/kg of lumefantrine for each dose. Tablets were administered according to the manufacturer’s instructions: 5 to 14.9 kg, 1 tablet; 15 to 24.9 kg, 2 tablets; 25 to 34.9 kg, 3 tablets; and >35 kg, 4 tablets.

Tablets were administered under medical supervision and with 100 mL of milk (the fat in the milk improves drug absorption). Patients were observed for 1 h after drug ingestion. The full dose was repeated if the patient vomited within 30 min, and a half-dose was given if the patient vomited within 1 h.

Patients who failed treatment were treated with intravenous (i.v.) quinine if severe (20-mg salt/kg of body weight loading dose followed by 10 mg/kg every 8 h) or oral quinine if uncomplicated (10 mg/kg three times daily for 7 days) according to national policy. Parenteral artesunate was not available.

All children were hospitalized for 3 days and followed up actively once a week for 42 days after treatment. Caretakers were invited to come back to the center or to contact the study nurse in the case that the child was unwell. If the patient did not report for the scheduled visits, every effort was made to locate him or her at the home address. At each visit, the medical history, clinical signs and symptoms, body temperature, and a blood sample for parasitemia were collected.

Sample size. For the calculation of the sample size, we assumed a cure rate of 95% with AL, 99% with DP, and 85% with AA. A sample size of 621 patients would have been adequate to detect a 10% difference between the standard treatment (AA) and AL or DP at the 5% level and with 90% power. The sample size was increased by 10% to allow for loss to follow-up (final sample size, n = 684).

Randomization, sequence generation, type, allocation concealment mechanism, and implementation. The randomization sequence, in blocks of 15, was computer generated and numerically sequenced. Opaque envelopes containing the study drug name were prepared at the Mahidol Oxford Tropical Medicine Research Unit (MORU), Bangkok, Thailand. Patients were enrolled by the study physician and assigned to treatment by the study nurse who opened the next consecutively numbered envelope. Once an envelope was opened, the patient was considered included in the study.

Outcome measurements. The primary outcome measure was the PCR-corrected cure rate by day 42. Secondary outcome measures were parasite and fever clearance and occurrence of adverse events (AE). Treatment outcome was established according to the standard WHO classification (8). Early treatment failure (ETF) was defined as (i) danger signs or severe malaria on day 1, 2, or 3, in the presence of parasitemia; (ii) parasitemia on day 2 higher than that on day 0, irrespective of axillary temperature; (iii) parasitemia on day 3 with axillary temperature of ≥37.5°C; and (iv) parasitemia on day 3 of ≥25% of count on day 0. Late clinical failure (LCF) was defined as (i) danger signs or severe malaria in the presence of parasitemia on any day between day 4 and day 42 in patients who did not previously meet any of the criteria of early treatment failure and (ii) axillary temperature of ≥37.5°C in the presence of parasitemia on any day between day 4 and day 42 in patients who did not previously meet any of the criteria of early treatment failure. Late parasitological failure (LPF) was defined as the presence of parasitemia between day 7 and day 42 with a temperature of <37.5°C in patients who did not previously meet any of the criteria of early treatment failure or late clinical failure. Adequate clinical and parasitological response (ACPR) was defined as absence of parasitemia on day 42, irrespective of axillary temperature, in patients who did not previously meet any of the criteria of early treatment failure, late clinical failure, or late parasitological failure.

Safety reporting was performed according to the ICH Harmonized Tripartite Guideline for Good Clinical Practice (9).

Laboratory methods. Asexual and sexual malaria parasites were identified and counted on Giemsa-stained thick films and reported per 200 leukocytes (WBC), assuming a total WBC count of 8,000/μL (10). Slides were declared negative after examination of at least 100 high-power microscopy fields. Parasite species was determined on the thin film. The laboratory technicians were blinded to the treatment received by individual patients. The blood film prepared during the screening was considered the admission slide.

Blood films were prepared at baseline and 6 and 12 h and then repeated every 12 h until 2 consecutive negative blood films were observed. Parasite clearance was assessed (i) as the time for the parasite count to decrease to 50% of its initial value (PC1/2) and (ii) as parasite clearance rate derived from the log-linear section of the log parasitemia-time curve and expressed as the parasite clearance half-life (PCt1/2, log10/parasite clearance rate).

To compare the PC1/2 measured in this study with the more recent data collected in 2013 during the Tracking Resistance to Artemisinin Collaboration (TRAC) project, all slides were read a second time after the study was terminated by the same microscopist using a different counting technique: if more than 20 parasites were seen on the thick smear after 10 fields, parasitemia per 1,000 erythrocytes (RBC) was counted on the thin smear. Below that threshold, parasites were counted on the thick smear per 300 WBC.

Hemoglobin was measured on admission using a portable photometer (HemoCue Hb201+; Angelholm, Sweden). Thereafter, the hematocrit was measured at baseline, daily during the hospitalization, and at days 7 and 14 of the follow-up by microhematocrit centrifugation (Hawksley Haematospin 1400; Hawksley & Sons, Ltd., United Kingdom).

Total and differential WBC counts were assessed daily during the hos-
pitalization and at day 7 and 14 of the follow-up (Sysmex automated hematology analyzer).

Liver function tests were performed, and aspartate aminotransferase (AST), alanine aminotransferase (ALT), and creatinine levels were measured from plasma at the hospital laboratories (SEAC-Screenmaster) at baseline and 48 h.

A dried blood spot (DBS) was prepared at admission, daily during the hospitalization, and at each follow-up visit for further molecular analysis.

Drug analysis. A random sample of tablets of DP was analyzed for content and quality at the Department of Pharmacology of MORU, and 2 ml of venous blood was taken at day 7 from 246 consecutive patients to measure plasma concentrations of lumefantrine and piperaquine.

Molecular analysis. Paired filter paper samples from enrollment and the follow-up day on which parasites were detected by microscopy were analyzed at the Shoklo Malaria Research Unit (SMRU) to distinguish between recrudescence and reinfection. Parasite DNA was purified (QiaAmp DNA microkit; Qiagen, United Kingdom), and the three polymorphic markers MSP-1, MSP-2, and GLURP were genotyped. A recrudescence infection was defined as one that matched in size at least one allele of each marker between the first and second samples. If any pair of alleles of a polyclonal primary infection was detected during a second episode, this was considered a recrudescence.

Ethical approval. The study was approved by the Oxford University Research Ethic Committee (OXTREC), the Institutional Review Board of Kinshasa School of Public Health (KSPH), and the Ministry of Public Health of DRC. A verbal consent was obtained from caretakers whose children fulfilled all inclusion criteria before enrolling the patient in the study.

The study was monitored regularly by a qualified internal monitor (MORU Clinical Trials Support Group) for adherence to Good Clinical Practice (GCP) regulations. All Investigators and the Research Ethic Committee (REC) of KSPH were notified of serious adverse events (SAEs).

Statistical analysis. Data were double entered in Microsoft Access 2007 and validated using Epi Info 6.4b (CDC, Atlanta, GA, USA). Statistical analyses were performed using STATA v.11 (StataCorp LP, College Station, TX). Descriptive statistics were used to summarize demographic data and baseline values. For the per-protocol analysis, χ² was used to compare proportions. Analysis of variance (ANOVA) was used for normally distributed continuous data and baseline values. For the per-protocol analysis, χ² was used to compare proportions. Analysis of variance (ANOVA) was used for normally distributed continuous data, and the nonparametric Kruskal-Wallis test was used to analyze continuous data with a nonnormal distribution.

For the intention-to-treat (ITT) analysis, the log rank test was used to test the equality of the survivor function across groups and Cox regression was used to estimate hazard ratio of infections posttreatment.

The overall fractional reduction in hematocrit was defined as the difference between the patient’s lowest level of hematocrit and that at baseline (i.e., pretreatment) divided by the hematocrit at baseline. The percentages of patients whose hematocrit fell >20% or 25% were compared between groups. No interim analyses for efficacy or futility were done.

RESULTS

ITT analysis and deviations from study protocol. Between September 2011 and November 2012, 684 patients were included in
the study, 228 in each treatment group. Forty-two patients (6.1%) discontinued the study: 5 children were withdrawn during the hospitalization because the families changed their minds and 37 were lost to follow-up between days 7 and 42 (DP, 16; AL, 10; AA, 16). One patient, in the AA group, died at day 29 from causes unrelated to malaria or the study drug. These cases were not included in the per-protocol analysis, and they were censored on the last day that the patients were visited by the doctor and tested for malaria in the intention-to-treat (ITT) analysis. The flow of patients through the study is outlined in the patient flow diagram (Fig. 1).

Baseline characteristics and treatment. At enrollment, patients had similar demographic, clinical, and parasitological characteristics (Table 1). The tablets of DP contained an average of 35.6 mg dihydroartemisinin (89%) and 306 mg piperaquine (95.5%). This was compared to the Eurartesim (Sigma Tau) product, which contained an average of 40.7 mg dihydroartemisinin (102%) and 300 mg piperaquine (94%).

Drug efficacy. (i) Per-protocol analysis. The cure rates by day 42 (primary outcome), PCR uncorrected, were similar in patients treated with AA (73.5%) and those treated with AL (70.6%), whereas the cure rate was significantly higher in patients treated with DP (86.8%) (Table 2). In the follow-up period, 145 children were diagnosed with a second episode of malaria (starting as early as day 16); most of these cases were new infections, and only 30 (21%) were confirmed by PCR as recurrent infections. Among the new infections, there were 12 cases of Plasmodium malariae and 1 of Plasmodium ovale. For 9 patients, the PCR was unsuccessful; as we could not ascertain if these 9 cases were new or recurrent infections, we excluded them from the PCR-corrected analysis. After correcting the results for the new infections, the cure rates were comparable in the three groups:

| TABLE 1 Baseline characteristics of children at enrollment by treatment group |
|-------------------|-------------------|-------------------|
| Characteristic     | AA                | AL                | DP                |
| No. of patients at admission | 228               | 228               | 228               |

| Results, PCR corrected: adequate clinical and parasitological response, no. (%) | 197 (93.4) | 202 (92.7) | 200 (94.3) | 0.78 |

* The samples were collected, but the PCR results were undetermined; cases were excluded from the PCR-corrected analysis.
93.4% for AA (95% confidence interval [CI], 89.1% to 96.3%), 92.7% for AL (95% CI, 88.4% to 95.7%), and 94.3% for DP (95% CI, 90.3% to 97.0%) (P = 0.76).

Early treatment failure occurred in three patients (0.5%), one in each arm. Data are reported also using day 28 cure rates as the endpoint (Table 3).

(ii) **Intention-to-treat analysis.** The ITT analysis showed similar results (log rank test for equality of survivor functions, PCR uncorrected, χ² = 18.83, P = 0.0001, and PCR corrected, χ² = 1.00, P = 0.61) (Fig. 2). The risk (hazard ratio) of having a second episode of malaria (either new or recurrent) in the follow-up period was 1.5 times higher in the AA arm and 2.4 higher in the AL arm than in the DP arm (P > 0.0001). The results were not affected by age or initial parasitemia.

**Fever clearance.** On admission, 26.8% of patients had fever (axillary temperature of ≥37.5°C). For the other patients, the parent or guardian reported a history of fever in the preceding 24 h as the main reason for seeking a doctor at the health center. After 24 h, 97% of children were afebrile and there was a significantly higher proportion of children with fever in the AL group at day 2 (P = 0.003; Table 4).

**Parasitemia clearance.** All treatments were associated with a rapid clearance of parasitemia. The parasite positivity rate (proportion of children with a positive slide at day 2) was significantly higher in the AL arm (P < 0.001; Fig. 3). Accordingly, the median PC₅₀ was significantly longer for AL (8.4 h; range, 0.2 to 23.9 h; n = 214) than for AA (5.7 h; range, 0.1 to 24.3 h; n = 204) and DP (6.5 h; range, 0.1 to 34.4 h; n = 212) (P < 0.001) (Table 5). The median PCₜ₁/₂ was 2.2 h (range, 1.0 to 6.3 h; n = 657) with no significant differences between arms, indicating similar efficacies of the three different artemisinin derivatives (P = 0.08) (Table 6).

**Gametocytemia.** On admission, 28.5% (n = 195/684) of patients were gametocytemic with no significant differences between groups. Treatment with AL resulted in lower gametocyte carriage rates than did the other two treatments in the follow-up period, days 7 to 21 (P < 0.001) (Fig. 4). In 7 children, gametocytemia was microscopically detectable from admission until day 35 (AA = 4, DP = 2, and AL = 1), and in 2 children treated with DP, it was detectable until day 42. In a number of children, gametocytes were not detected on admission blood smears but became apparent in the first 72 h of treatment with no significant differences between

![FIG 2](image-url) Intention-to-treat analysis: Kaplan-Meier plots of failure rates (y axis) without (a) and with (b) PCR correction.

![FIG 3](image-url) Parasite positivity rate (y axis) by day (x axis) and treatment group.
arms. New appearance of gametocytes was, however, uncommon from day 7 onward.

**Hematology.** The mean packed cell volume (PCV) at admission was 30.1% (95% CI, 29.8% to 30.5%; range, 13% to 42%). In the first week, there was an overall mean fractional reduction in the PCV of 10% (standard deviation [SD], 8.3) with no differences between arms ($P = 0.65$) (Table 7). Hyperparasitemic children ($\geq 150,000/\mu l$) were those most affected, with a mean fractional reduction of 15.1% (95% CI, 7.4 to 8.7) compared to 8.1% (95% CI, 13.8 to 16.3) in those who were not hyperparasitemic ($P < 0.001$).

A reduction of > 25% of the initial PCV value was observed in 14.9% of hyperparasitemic children and 2.3% of nonhyperparasitemic children ($P < 0.001$).

Ten patients developed decompensated anemia within 4 days of recruitment and required a blood transfusion: 3 in the AA group, 4 in the AL group, and 3 in the DP group ($P = 0.62$). The risk of receiving a blood transfusion was 6.5 times higher in the hyperparasitemic children (95% CI, 2.90 to 22.3; $P = 0.005$). By day 14, the levels were comparable to those at admission in all patients.

The median WBC counts were similar between the treatment groups on recruitment and at each day of follow-up with an increase from day 0 to day 7 to normal values (Table 8). Neutrophil counts decreased gradually from baseline values until day 14 with no differences between groups on any day. Mild neutropenia ($< 1,000$ neutrophils/$\mu l$) was observed in 2.5% of patients at enrollment, and between days 1 and 7, the neutrophil count fell below 1,000/$\mu l$ in 18% of patients (123/684) with no differences between groups ($n = 40$ in AA, 40 in AL, and 43 in DP; $P = 0.92$). Fourteen of these patients developed severe neutropenia (< 500 neutrophils/$\mu l$) (2, 4, and 8 in the AA, AL, and DP groups, respectively; $P = 0.13$).

**Hepatotoxicity.** Mean serum levels of aspartate aminotransferase (U/liter), alanine aminotransferase (U/liter), and creatinine (mg/dl) were similar at baseline among groups. With minor fluctuations (a trend toward a reduction for AST and ALT), the mean levels at day 2 remained similar to those of day 1 with no statistical differences between groups (data not shown).

**Tolerability.** During the first day, children treated with DP vomited within 1 h of the first dose significantly more often ($n = 21; 9.2%$) than did children treated with AA ($n = 10; 4.4%$) or AL ($n = 5; 2.2%$) ($P = 0.03$). The second dose of AL—administered after 8 h—was vomited in seven cases, and taking this into account, the overall difference between treatments during the first day was not significant ($P = 0.06$). These children were all given a second dose of the drug. On the second day, there was no difference in vomiting postdose between children treated with AA (15; 6.6%) and those treated with DP (17; 7.5%), whereas in the AL arm only 2 (0.9%) cases vomited after the first dose and none after the second dose ($P = 0.02$).

**Adverse events.** At least one adverse event was reported in 37.4% of patients during the posttreatment period that was not present on admission or increased in intensity and was classified as possibly or probably related to the study drug. Most AEs were graded as of minor or moderate intensity. The most frequent AEs were weakness, anorexia, and gastrointestinal disorders (nausea, vomiting, abdominal pain, and diarrhea). However, these symptoms overlap known malaria symptomatology. Anorexia and weakness were reported more frequently in children treated with AA than in those treated with DP and AL during the second and third days of treatment (day 1, 15.2% [34/224] for AA, 5.3% [12/227] for AL, and 5.8% [13/228] for DP [$P = 0.0001$], and day 2, 8.2% [17/207] for AA, 2.3% [5/220] for AL, and 4.0% [9/224] for DP [$P = 0.013$]). There were otherwise no differences in the numbers of AEs between treatment groups. In 17 cases, the adverse event was graded as severe or life-threatening. All cases were classified as unlikely to be related to the study treatment. Ten patients developed decompensated anemia during the hospitalization and required a blood transfusion (described above). There was one case of severe skin eruption 18 days posttreatment (DP), one case of chickenpox 12 days posttreatment (AL), 1 case of abscess 11 days posttreatment (DP), 1 case of leukocytosis 2 weeks posttreatment (AL), and 3 cases of asthenia (2 AL and 1 AA). One child in the AA group died in a different hospital at day 29. The cause of death was unknown, but the death was considered unlikely to have been caused by either malaria or the drug treatment.

### Table 5: Time (hours) to clear 50% of parasitemia by treatment

| Treatment group | No. of observations used for estimation | Time (h) to clear 50% of parasitemia |
|-----------------|----------------------------------------|-------------------------------------|
|                 | Median | Range       | IQR*     |
| AA              | 204    | 5.71        | 0.09–24.26 | 5.39     |
| AL              | 214    | 8.44        | 0.18–23.85 | 5.64     |
| DP              | 212    | 6.54        | 0.08–34.40 | 5.12     |
| Total           | 630    | 7.31        | 0.08–34.40 | 5.63     |

* IQR, interquartile range.

### Table 6: Slope half-life (based on the slope of the log-linear portion of the parasite clearance curve)

| Treatment group | No. of observations used for estimation | Slope half-life (h) |
|-----------------|----------------------------------------|---------------------|
|                 | Median | Range       | IQR*     |
| AA              | 214    | 2.15        | 1.05–4.35 | 0.87     |
| AL              | 223    | 2.23        | 1.05–6.32 | 0.73     |
| DP              | 220    | 2.13        | 0.97–4.85 | 0.76     |
| Total           | 657    | 2.18        | 0.97–6.32 | 0.82     |

* IQR, interquartile range.

### Figure 4: Gametocyte positivity rate (y axis) by treatment days 0 to 42 (x axis).
 Plasma lumefantrine levels at day 7. One hundred twenty-one samples of venous blood were collected at day 7 from patients who received AL (Table 9). The median concentration of lumefantrine in the blood was 377 ng/ml (range, 57.1 to 1,150 ng/ml). Drug levels were positively correlated with body weight \((r = 0.22; \text{test for trend}, P = 0.005)\). The plasma level was significantly lower in children weighing \(<15\text{ kg (median, 309 ng/ml; range, 57.1 to 1,080}; n = 87)\) than in those weighing \(\geq 15\text{ kg (median, 473 ng/ml; range, 108 to 1,150}; n = 34; P = 0.01)\). Accordingly, 43.7% of children weighing \(<15\text{ kg had a plasma level of } \geq 280\text{ ng/ml, considered the cutoff for therapeutic efficacy (11)}\), compared to 20.6% in those weighing \(\geq 15\text{ kg (} P = 0.018)\). The 7 children in this subsample with a PCR-confirmed recrudescence had a median level of 429 ng/ml (range, 147 to 703 ng/ml), not significantly different from those who successfully cleared the infection (376 ng/ml; range, 57.1 to 1,150; \(P = 0.8; n = 114\)).

 Plasma piperaquine levels at day 7. One hundred twenty-five samples of venous blood were collected at day 7 from patients who received AL (Table 10). The median concentration of piperaquine in the blood was 280 ng/ml, compared to the value at admission by treatment group.

## DISCUSSION

The efficacies of the three combination therapies tested in this trial were similar. The proportion of children with an adequate clinical and parasitological response was 93% for AL and 94% for DP, both rarely used in the area. These cure rates are similar to that of AA (93%), which has been extensively used in DRC since its introduction in 2006.

The PCR-corrected day 28 cure rate for AL in the present study was 96.8%, which is comparable to the 97.9% day 28 cure rate observed in the same area 3 years previously (13).

In the subsample analyzed, the drug level of piperaquine at day 7, reflecting the concentration of drug to which residual parasites are exposed and thus predictive of outcome, was suboptimal in 47% of patients. This confirms previous results (6, 14) showing that as small children have a higher body-weight-normalized oral clearance, they need a higher dose than the one currently recommended. Of the children who received artemether-lumefantrine, 37% had a suboptimal day 7 lumefantrine level, with the smaller children having the lowest levels. These results are comparable to those observed in Uganda (15). As there was no evidence of delayed parasitemia clearance suggestive of artemisinin resistance,
the PCR-confirmed treatment failures observed in the current study are likely caused by either low drug exposure, as suggested by the pharmacokinetic (PK) results, or parasite resistance to the nonartemisinin partner drug. The former is much more likely. Moreover, in high-transmission areas, the chances that the recurrent infection contains a parasite with the same genotype as that in the primary infection are higher than those in low-transmission areas. This, along with the persistence of gametocytes in the blood, can lead in some cases to a misclassification of recurrent infections as recrudescences (16).

In this clinical trial, we measured efficacy of treatments administered under supervision, with a glass of milk, and retreatment was given if the first dose was vomited. Drug exposure, in a nontrial setting (generally unsupervised), is expected to be lower (15). Dose optimization and schedule changes are a priority for the ACT, especially in small children, to ensure adequate drug exposure (14, 17).

Although the efficacies in terms of ACPR rates of the three ACTs were comparable, children treated with DP were at lower risk of having a second episode of malaria during the follow-up period because of the longer posttreatment prophylactic effect of DP related to the longer plasma half-life of piperaquine. This chemoprophylactic effect is important in areas of endemicity such as the study area and makes this drug a good candidate for replacing the recommended dosage of DP provides suboptimal piperaquine plasma concentrations, particularly in small children.

**Acknowledgments**

We thank our young patients and their families, the study staff at Kingasani Research Centre, and the hospital staff and management at Kingasani Hospital. We thank Kevin Marsh, KEMRI, for donating amodiaquine-artesunate and Guillin Pharmaceutical, China, for donating dihydroartemisinin-piperaquine.

The authors have no conflicts of interest concerning the work reported in this paper.

The study was financed by the Wellcome Trust, United Kingdom. M.A.O. and C.I.F. conducted the study and acquired data; K.W. conducted molecular analysis; J.T. conducted pharmacological analysis; C.I.F. conducted statistical analysis; C.I.F., K.A.T., A.M.D., F.N., N.J.W., N.P.J.D., and J.T. prepared the manuscript. All coauthors read the final version of the manuscript.
