Relaxin influences ileal muscular activity through a dual signaling pathway in mice

Eglantina Idrizaj, Rachele Garella, Fabio Francini, Roberta Squecco, Maria Caterina Baccari

AIM
To investigate the signaling pathways involved in the relaxin (RLX) effects on ileal preparations from mice through mechanical and electrophysiological experiments.

METHODS
For mechanical experiments, ileal preparations from female mice were mounted in organ baths containing Krebs-Henseleit solution. The mechanical activity was recorded via force-displacement transducers, which were coupled to a polygraph for continuous recording of isometric tension. Electrophysiological measurements were performed in current- and voltage-clamp conditions by a microelectrode inserted in a single smooth muscle cell (SMC) of the ileal longitudinal layer. Both the membrane passive properties and inward voltage-dependent L-type Ca²⁺ currents were recorded using suitable solutions and voltage stimulation protocols.
RESULTS
Mechanical experiments showed that RLX induced a decay of the basal tension and a reduction in amplitude of the spontaneous contractions. The effects of RLX were partially reduced by 1H-[1,2,4]oxadiazolo[4,3-a]-quinoxalin-1-one (ODQ) or 9-cyclopentyladenine mesylate (9CPA), inhibitors of guanylate cyclase (GC) and adenylate cyclase (AC), respectively, and were abolished in the concomitant presence of both drugs. Electrophysiological experiments demonstrated that RLX directly influenced the biophysical properties of ileal SMCs, decreasing the membrane conductance, hyperpolarizing the resting membrane potential, reducing the L-type calcium current amplitude and affecting its kinetics. The voltage dependence of the current activation and inactivation time constant was significantly speeded by RLX. Each electrophysiological effect of RLX was reduced by ODQ or 9CPA, and abolished in the concomitant presence of both drugs as observed in mechanical experiments.

CONCLUSION
Our new findings demonstrate that RLX influences ileal muscle through a dual mechanism involving both GC and AC.

Core tip: Up to now relaxin (RLX) was described to act only through the NO/guanylate cyclase (GC)/cGMP/PKG pathway in different gastrointestinal tracts. The results of the present study, achieved on mice ileal preparations and carried out by a combined mechanical and electrophysiological approach, demonstrate for the first time that both GC and adenylyl cyclase are involved in the effects of RLX in this intestinal region. The activation of this dual signaling pathway by RLX might represent a reinforcing (redundant) myorelaxant mechanism in the ileum, underlying the physiological importance of the hormone and leading to speculate translational perspectives in the treatment of intestinal dysmotilities.

INTRODUCTION
It is widely recognized that the effects of the peptide hormone relaxin (RLX) are not limited to reproductive organs[4-6]. Receptors of the RLX family peptides have been indeed identified in both reproductive and non-reproductive tissues[7-9], including human and rodent intestine[7-9]. Concerning on the molecular mechanism of action of RLX on the target cells, multiple intracellular signaling systems appear to be engaged[10,11]. In some cells, such as the smooth muscle of reproductive tissue, the effects of the hormone RLX are due to the activation of adenylyl cyclase (AC)[12-15] leading to increase of the cyclic adenosine monophosphate (cAMP) levels. However, in some other different preparations, such as in vascular and intestinal smooth muscle, the mechanism of action activated by RLX occurs through the endogenous nitric oxide (NO) synthesis[16-23] and leads to increased levels of cyclic guanosine monophosphate (cGMP).

Particularly, in the gastrointestinal tract of mice, RLX has been reported to modulate gastric and colonic smooth muscle activity through the L-arginine/NO pathway[9,24-26]. NO, synthesized under the catalytic action of nitric oxide synthases (NOS)[27], is known to cause gastrointestinal relaxation[28] and its altered production has been reported to be involved in different motor disorders[29]. However, Bani et al[30] raised the possibility that in the ileum, at variance with gastric and colonic preparations, the NO signaling pathway could not be the only one activated by the hormone, suggesting the involvement of additional pathways that have not been fully elucidated yet in this preparation. In this regard, the involvement of AC, in addition to guanylyl cyclase (GC), in the effects of RLX has been reported in rat and guinea pig airways[31] as well as in human vascular cells[10].

On these grounds, the present study was designed to investigate for the first time, if AC/CAMP, besides the NO/GC/cGMP, could be a further signaling pathway involved in the effects of RLX on ileal smooth muscle. To evaluate this possibility, we performed experiments by a combined mechanical and electrophysiological approach. Particularly, for the first time we investigated the ability of RLX to induce changes of smooth muscle cell (SMC) biophysical properties in ileal preparations through the electrophysiological technique. Moreover, we studied the effects of RLX on the L-type Ca2+ current, I_{Ca,L}, that is supposed to be the main voltage-dependent source for Ca2+ entry useful for the activation of the SMC contractile machinery[32]. This knowledge may contribute to a better understanding of the mechanisms engaged by the hormone to modulate intestinal motility and may help in the design of further therapeutic strategies for the treatment of motor disorders.

MATERIALS AND METHODS

Animals
Experiments were performed on 8- to 12-wk-old female mice (CD1 Swiss strain; Envigo, Udine, Italy). The animals were kept under the following conditions: 12-h light/12-h dark photoperiod, constant
temperature (21 ± 1 °C), and standard laboratory feed.

After 1 wk of acclimatization, the mice underwent assessment of the phase of the estrous cycle by light microscopic examination of vaginal smears stained with Papanicolaou stain, according to the method of Austin and Rowlands[33]. Only mice in proestrus or estrus (i.e., the estrogen-dominated phases of the ovarian cycle) entered the experiments. This choice was made because estrogen is known to favor RLX responsiveness of several target organs and tissues[34]. The mice were killed by prompt cervical dislocation to minimize animal suffering. According to the procedure reported in previous paper[30] the mouse abdomen was opened, the distal ileum was removed and its content was cleaned with a physiological solution.

Mechanical experiments

For the functional studies, segments of the distal ileum (within 30 mm from the ileocaecal valve) were isolated and placed in Krebs-Henseleit solution, which consisted of 118 mmol/L NaCl, 4.7 mmol/L KCl, 1.2 mmol/L MgSO4, 1.2 mmol/L KH2PO4, 25 mmol/L NaHCO3, 2.5 mmol/L CaCl2, and 10 mmol/L glucose pH 7.4, and bubbled with 95% O2/5% CO2. Two whole full-thickness, transversely cut, ileal segments (10 mm in length) were dissected from each animal and placed in 5-mL organ baths containing Krebs-Henseleit solution gassed with 95% O2/5% CO2, while the temperature was maintained within a range of 37 ± 0.5 °C. The preparations were mounted in the direction of the longitudinal muscle layer and the continuous recording of isometric tension was achieved by a force displacement transducer (FT03; Grass Instrument) coupled to a polygraph (7K; Grass Instrument). The preparations were allowed to equilibrate for at least 1 h under an initial load of 1.5 g. During this period, the preparations underwent repeated and prolonged washes with Krebs-Henseleit solution to avoid accumulation of metabolites in the organ baths.

Electrophysiological experiments

For electrophysiological recording a full-thickness ileal strip was distended and pinned to a Sylgard (Dow Corning, Midland, MI, United States)-coated dissecting Petri dish filled with Krebs-Henseleit solution. First, we pinned the mucosal side up to dissect carefully the mucosa and submucosa away from a dissecting microscope. The residual tissue was re-pinned serosal side up and the connective tissue was removed in order to expose the smooth muscle layer. The obtained tissue was finally pinned, serosal side up, in the recording chamber with a Sylgard floor and a glass microelectrode was inserted in a cell of the longitudinal smooth muscle layer. The tissue was continuously superfused (Pump 33, Harvard Apparatus) at a rate of 1.8 mL min⁻¹ with the external solution used.

Conventional high resistance microelectrodes were used according to the previously published procedure[30,35]. Microelectrodes were obtained by using a micropipette vertical puller (Narishige PC-10) from borosilicate glass (GC 100-7.5; Clark) and were filled with the following control physiological solution (mmol/L): KCl 130, NaH2PO4 10, CaCl2 0.2, EGTA 1, MgATP 5 and HEPES/KOH 10. Once filled, the pipette resistance measured 60-70 MΩ. The pH was set to 7.4 with NaOH and to 7.2 with tetraethylammonium (TEA) hydroxide for bath and pipette solution, respectively.

To record RMP in current-clamp and the cell membrane passive properties in voltage-clamp mode we used the extracellular Krebs-Henseleit solution. To record only Ca²⁺ currents we bathed the ileal muscle strip in a Na⁺- and K⁺-free high-TEA solution (mmol/L): 10 CaCl2, 145 TEABr and 10 HEPES and the microelectrode was filled by the following solution (mmol/L): 150 CsBr, 5 MgCl2, 10 EGTA, 10 HEPES. Nifedipine (10 μmol/L) was used to block L-type Ca²⁺ current, Ica,L. Heptanol (1 mmol/L) was consistently used to block gap junctional currents of the functional syncytium and to record membrane passive properties and ionic currents elicited only from the impaled cell[35,36].

The current amplitude was always normalized to cell linear capacitance Cm (in pA/pF) to consent the evaluation of test current recorded from cells of different size; in fact, Cm is usually considered an index of cell-surface area presuming that membrane-specific capacitance has a constant value of 1 μF/cm².

Pulse protocols of stimulation

By using the current clamp mode of our amplifier and stimulus waveform with I = 0 pA we recorded the SMC resting membrane potential, before and after drug stimulation. Protocol of recording consisted of 8 episodes, having a sampling interval of 20 ms and a total duration of 5.29 min. The inter-episode interval was 1 min.

The membrane passive properties, membrane conductance (Gm) and Cm, were consistently estimated in voltage clamp mode by applying two step voltage pulses 75 ms long to -80 and -60 mV starting from a holding potential (HP) of -70 mV. Their values were calculated as detailed in Squecco et al[37]. Always in this mode, ionic currents were evoked by the following pulse protocols: Ica,L activation was evoked on the SMC held at -80 mV, and 1-s long step pulses were applied in 10-mV increments from -70 to 50 mV. For each episode, the first 100 ms of the trace had a sampling interval of 50 μs, and the remaining of 1 s. The interval between episodes was 20 s to allow recovery. Icax,L inactivation was investigated by a two-pulse protocol with a 1-s pre-pulse to different voltages followed by 1-s test pulse to 10 mV as reported in our previous works[9,35]. When we applied the two-pulse protocol, we used again a 20-s interval between stimulating episodes to allow recovery. Capacitive, linear leak and voltage-independent ionic currents were cancelled on-line using the P/4 procedure.
µmol/L), 1H-[1,2,4] oxadiazolo[4,3-a]-quinoxalin-1-one (ODQ, 1 μmol/L), 9-cyclopentyladenine mesylate (9CPA, 100 μmol/L) and relaxin (RLX, 50 nmol/L). All drugs were obtained from Sigma Chemical (St. Louis, MO, United States), except for highly purified porcine RLX (2500-3000 U/mg) that was generously provided by Dr. O. D. Sherwood (University of Illinois, Urbana, IL, United States). Solutions were prepared on the day of the experiment, except for TTX, for which a stock solution was kept stored at -20 ℃. Drugs concentrations are given as final bath concentrations. The concentration of porcine RLX used was in the range of that formerly demonstrated to be effective in murine gastrointestinal preparations [9,30,38-40].

To evaluate the steady-state ionic current activation through the voltage dependent channels we used the following equation:

\[ I_a(V) = \frac{G_{\text{max}} (V-V_{rev})}{1 + \exp\left(\frac{V_a-V}{k_a}\right)} \]

The following was used for the steady-state current inactivation:

\[ I_h(V) = \frac{I}{1 + \exp\left(-\frac{V_h-V}{k_h}\right)} \]

where \( G_{\text{max}} \) represents the maximal conductance for \( I_a \); \( V_{rev} \) is the apparent reversal potential; \( V_a \) and \( V_h \) are the voltages causing the half-maximal activation and inactivation, respectively; \( k_a \) and \( k_h \) are steepness factors.

**Drugs**

We used tetrodotoxin (TTX, 1 μmol/L), nifedipine (10 μmol/L), 1H-[1,2,4] oxadiazolo[4,3-a]-quinoxalin-1-one (ODQ, 1 μmol/L), 9-cyclopentyladenine mesylate (9CPA, 100 μmol/L) and relaxin (RLX, 50 nmol/L). All drugs were obtained from Sigma Chemical (St. Louis, MO, United States), except for highly purified porcine RLX (2500-3000 U/mg) that was generously provided by Dr. O. D. Sherwood (University of Illinois, Urbana, IL, United States). Solutions were prepared on the day of the experiment, except for TTX, for which a stock solution was kept stored at -20 ℃. Drugs concentrations are given as final bath concentrations. The concentration of porcine RLX used was in the range of that formerly demonstrated to be effective in murine gastrointestinal preparations [9,30,38-40]. The choice of GC...
and AC inhibitors was based on previous literature\cite{9,41} and their related concentration was in the range of that previously proven to be effective\cite{9,42}.

Data analysis and statistical tests
As previously reported\cite{30,38}, in the mechanical experiments, amplitude of spontaneous contractions and variations in basal tension are expressed as grams.

For electrophysiological experiments, mathematical and statistical analysis of data was performed by SigmaPlot (Jandel Scientific) and pClamp9 (Axon Instruments). Statistical analysis was performed by Student’s t-test to compare two experimental groups or one-way ANOVA followed by Newman-Keuls post-test for multiple comparisons. The number of muscle preparations/cells is designated by \( n \) in the results. Results are means \( \pm \) SE. \( P \leq 0.05 \) was considered statistically significant.

RESULTS
Mechanical experiments
Effects of relaxin on the mechanical activity: At basal tension, ileal preparations (\( n = 24 \), from 12 mice) showed spontaneous and rhythmic phasic contractions (mean amplitude 0.60 \( \pm \) 0.03 g), indicating their myogenic nature, and reduced by 10 \( \mu \)mol/L nifedipine (0.35 \( \pm \) 0.05 g).

Addition of RLX (50 nmol/L) to the bath medium (\( n = 18 \), from 9 mice) caused a clear-cut decay of the basal muscle tension (62.3\% \( \pm \) 3.1\%) and a reduction in amplitude (36.1\% \( \pm \) 1.8\%) of the spontaneous contractions (Figure 1). The action of the hormone on basal tension and on spontaneous activity was just evident 10 min and 20 min, respectively, after its addition to the bath medium. The influence of RLX on ileal motility was long lasting, because its effects could still be revealed 1 h after the peptide addition to the organ baths (longer time not observed). The effects of the hormone on basal muscle tension and spontaneous contractions were unaffected by TTX (60\% \( \pm \) 3.1\% and 37.2\% \( \pm \) 1.5\%, respectively) whereas they were no longer detectable 10 min after the addition of nifedipine (\( P > 0.05 \) in respect to nifedipine alone) to the bath medium.

Addition of the GC inhibitor ODQ (1 \( \mu \)mol/L) to the bath medium did not induce significant effects (\( P > 0.05 \)). In the presence of ODQ (1 \( \mu \)mol/L) both spontaneous contractions and muscle basal tension were only reduced by 50 nmol/L RLX (Figure 1), thus suggesting the contribution of other signaling paths in the hormone action. We therefore tested the possible involvement of the AC pathway, employing the AC
inhibitor 9CPA (100 μmol/L): 9CPA had not “per se” significant effects ($P > 0.05$) but reduced the actions of RLX although it was unable to completely restore the control mechanical activity (Figure 1). RLX added to the bath medium in the presence of ODQ plus 9CPA had no longer effects on both muscle tension and spontaneous contractions (Figure 1).

**Electrophysiological experiments**

**Influence of relaxin on the smooth muscle cell membrane passive properties:** To further test the possible direct action of RLX on ileal SMC, we investigated the effects of the hormone on the SMC resting membrane properties. RLX did not alter significantly $C_m$ (Figure 2A) but decreased $G_m$ and the specific conductance ($G_m/C_m$) values (Figure 2B-C). Addition of ODQ (1 μmol/L) or 9CPA (100 μmol/L) to the external recording medium did not affect significantly the membrane passive properties compared to the untreated control ($P > 0.05$). The effects of RLX on $G_m$ and $G_m/C_m$ were partially inhibited when was added in the presence of ODQ or 9CPA, and were completely abolished in their concomitant presence, reaching values similar to those observed in

---

**Figure 3** Effects of relaxin, in the absence or in the presence of oxadiazolo[4,3-a]-quinoxalin-1-one and 9-cyclopentyladenine, on membrane potential recorded from smooth muscle cell of the mouse ileum. Typical tracings of membrane potential from four different single ileal SMCs. A-D: Irregular waves of MP recorded in control condition. RLX addition (arrow) induced a persistent hyperpolarization occurring right after about 2 min from its application (A); The hyperpolarization caused by RLX was reduced in the presence of ODQ (B), 9CPA (C) and was abolished when both blockers were concomitantly present in the bath solution (D). Breaks in X-axis (and consequently in the MP traces) indicate the end of each episode, RLX: Relaxin; ODQ: Oxadiazolo[4,3-a]-quinoxalin-1-one; 9CPA: 9-cyclopentyladenine.
control condition (Figure 2B and C).

**Effects of relaxin on smooth muscle cell resting membrane potential:** We then evaluated the RLX effects on resting membrane potential (RMP) of SMCs, to test its role on cell excitability. In control condition, the membrane potential showed spontaneous irregular slow waves (n = 22 cells; 11 strips from 5 mice) (Figure 3). These waves of the membrane potential lasted 0.4-1.1 min and showed alternating periods of very low (0.5 ± 0.1 wave/min) and higher (1.1 ± 0.2 wave/min) frequencies lasting 5-6 and 15 min, respectively. The maximal hyperpolarization value of the waves was considered as the RMP. The mean amplitude of the irregular waves was 37.5 ± 8 mV.

After RLX addition to the bath solution, the irregular waves were still recorded but the membrane potential showed a hyperpolarization trend that was already appreciable 1-3 min after its application (Figure 3A). The irregular waves were always recorded during the hyperpolarization due to RLX, and maintained a similar amplitude, duration and frequency.

The statistical analysis of the RMP values is reported as histograms in Figure 2D for each experimental condition. Noteworthy, the mean value of control RMP was -53.4 ± 7 mV and it reached -91.1 ± 12 mV in the presence of RLX, clearly indicating a statistically significant hyperpolarization. Furthermore, being the size of the irregular wave similar to the control value (41.5 ± 8 mV), the positive peak of the waves was different in RLX compared to control (Figure 3): it reached a mean value of -20 ± 5 (range from -30 to -12) mV in control and -49.6 ± 16 (range from -75 to -25 mV) mV after RLX addition. This observation indicates that RLX does not influence the amplitude and the frequency of the slow potentials and suggests that RLX may hamper the probability to reach a depolarized voltage threshold suitable for ion channels activation. Consequently, since the slow voltage waves arise from a voltage value that is under threshold for the voltage-dependent L-type Ca\(^{2+}\) current activation (see below) and their amplitude in this hyperpolarized state is not altered, we could deduce that they are not due to voltage-dependent channels opening.

In order to investigate the possible effectors involved in these RLX effects, we used the GC and AC inhibitors also in this set of experiments. Again, addition of ODQ or 9CPA alone to the external solution did not modify significantly the wave amplitude, duration, frequency and the resting membrane potential compared to the untreated control (Figure 3) (P > 0.05). RLX added at least 5 min after ODQ or 9CPA, hyperpolarized the RMP to a lesser extent (Figure 3B and C) compared to RLX alone, suggesting the involvement of both GC and AC pathways. Once again, in agreement with the mechanical results, RLX added in the presence of both inhibitors was no more able to induce hyperpolarization (Figures 2D and 3D).

**Influence of relaxin on the voltage-dependent Ca\(^{2+}\) current:** The effects of the hormone were then evaluated on the inward voltage-dependent
Ca\textsuperscript{2+} currents, supposed to be the chief path for Ca\textsuperscript{2+} entry useful to trigger the contractile machinery in intestinal SMCs. Notably, in our experiments we did not consistently record TTX-sensitive Na\textsuperscript{+} current. Accordingly, to better put in evidence the appearance of voltage-dependent Ca\textsuperscript{2+} currents, we used appropriate filling pipette solution and a bath recording high TEA-Ca\textsuperscript{2+} solution (see Materials and Methods section). The time course of typical current traces recorded from a control cell and after RLX addition is shown in Figure 4 (Aa and Ab, respectively). Since this kind of current had a high voltage threshold (about -30 mV), a slow activation and inactivation, and was blocked by nifedipine we assumed that it was an L-type Ca\textsuperscript{2+} current (\(I_{Ca,L}\)). No T-type Ca\textsuperscript{2+} current was revealed in our preparations. It can be clearly seen (Table 1, Figures 4A and 5A) that RLX reduced the maximal peak current amplitude (\(P < 0.05\)) and the time to peak (\(t_p\)) \((P < 0.01)\). Moreover, the hormone shifted the mean voltage eliciting the maximal peak current size (from 17.5 ± 2 to 20.1 ± 2 mV).

To evaluate the general behavior of the phenomenon, we plotted our experimental data related to all the experiments done in the \(I-V\) relationship, reporting the normalized mean \(I_{Ca,L}\) maximal amplitude for any voltage step applied (Figure 5A). The analysis of the \(I-V\) plot confirmed that RLX caused the decrease of current amplitude and a shift of the \(V_a\) and \(V_i\) values towards more positive potential (Table 1). The ODQ or 9CPA pre-treatment did not completely abolish the effect of RLX, but slightly reduced the size decrease (Figure 4) and the alteration of the \(V_a\) and \(V_i\) values. These parameters completely recovered the control values in the presence of ODQ plus 9CPA (Table 1, Figure 5C and D).

The voltage dependence of the current activation time constant, \(\tau_a\) (Figure 5C) as well as that of inactivation, \(\tau_h\) (Figure 5D) was significantly speeded by RLX. Particularly, the ODQ pre-treatment did not entirely eliminate the effects of RLX on \(\tau_a\) that did not result significantly different to that recorded in the presence of RLX alone, whereas 9CPA resulted more effective in counteracting RLX effects (Figure 5C) which were abolished in the concomitant presence of the inhibitors. Instead, the action of RLX on \(\tau_h\) was similarly prevented by each of the inhibitors (Figure 5D).

The effects of RLX and those of the effector inhibitors on \(I_{Ca,L}\) voltage dependence were analyzed by the steady-state activation and inactivation curves (Figure 5B): RLX shifted the activation and inactivation curves towards more positive potentials making this latter more U-shaped for depolarized voltages. All the Boltzmann parameters were only partially reverted to control values when RLX was added after ODQ or
Idrizaj E et al. Relaxin and ileal smooth muscle

Table 1 Boltzmann parameters of I_{sca} activation and inactivation in a smooth muscle cell in control (Ctr), in the presence of relaxin (RLX) alone or RLX with ODQ (ODQ + RLX), 9CPA (9CPA + RLX) and ODQ + 9CPA (ODQ + 9CPA + RLX)

| Parameters        | Ctr       | RLX       | ODQ + RLX  | 9CPA + RLX  | ODQ + 9CPA + RLX |

In the U shaped inactivation curves (h) the best fit to the data is obtained by the sum of two Boltzmann terms whose parameters are indicated with the subscript \(h\) for the term at negative potential, and \(2h\) for the term at positive potential; the amplitude of the normalized second term, \(I_{0}\) (Norm), was evaluated at 50 mV. \(P < 0.05\), \(P < 0.01\) and \(P < 0.001\) RLX compared to the related control; \(P < 0.05\), \(P < 0.01\) and \(P < 0.001\) compared to RLX. Data for Ctr \((n = 20\) cells, 10 strips from 10 mice\), for RLX \((n = 20\) cells, 10 strips from 10 mice\), for ODQ + RLX \((n = 16\) cells, 9 strips from 10 mice\), for 9CPA + RLX \((n = 15\) cells, 8 strips from 5 mice\) and for ODQ + 9CPA + RLX \((n = 16\) cells, 9 strips from 5 mice\).

9CPA and recovered when the hormone was applied in the concomitant presence of both the inhibitors. ODQ or 9CPA added alone to the bath solution did not cause appreciable differences in current records compared to control records \((P > 0.05)\). The best fit parameters, statistical analysis and number of analyzed cells are reported in Table 1.

**DISCUSSION**

The present mechanical and electrophysiological results indicate, for the first time, that the hormone RLX is able to influence the ileal smooth muscle activity from female mice acting through a dual pathway, where both CG and AC are involved.

We previously observed in the same kind of preparation\(^{[30]}\) that RLX increased the expression of both inducible and endothelial nitric oxide synthases but its depressive effects were not completely abolished by the NO synthesis inhibitor L-NNA. These observations indicated that the inhibitory effects of the hormone mainly occurred through the activation of intrinsic NO biosynthesis but, at the same time, suggested the involvement of additional signaling pathways. Accordingly, the mechanical results of the present study show that the decay of the muscular tension and the decrease in amplitude of the spontaneous contractions caused by RLX are reduced not only by ODQ but also by 9CPA leading to the novel finding that, other than GC, AC too is involved in the effects of the hormone on ileal motility. The involvement of other signaling pathways, besides the NO/cGMP, may account for the site-related actions of RLX in the modulation of the activity of the different GI tract in mice\(^{[26]}\). In this view, regional differences among mouse small intestine tracts concerning the nitrergic mechanisms mediating inhibitory control of longitudinal SMC contraction have been reported: the effects of NO donors were indeed completely abolished by ODQ in jejunum but only partially eliminated in ileum, suggesting the involvement of an additional pathway\(^{[30]}\).

Another novel aspect of this research is represented by the electrophysiological results demonstrating, for the first time in ileal preparations, that RLX was able to act directly on the SMC, by influencing its biophysical membrane features and the voltage-dependent L-type Ca\(^{2+}\) channels properties. Regarding to the biophysical properties, the observations that RLX decreases the total and specific membrane conductance and hyperpolarizes the membrane potential definitely strengthen each other, since the decrease of the resting membrane conductance can indicate the reduction of aspecific cationic influxes that, in turn, hampering the entrance of positive charges may favor RMP hyperpolarization. They are also in good agreement with the depressive mechanical effects observed in this study, since changes of the RMP value lead to the reduction of the contractile activity that strictly depends on membrane potential (electro-mechanical coupling)\(^{[44]}\). However, the signaling cascade associated to membrane hyperpolarization is complicated and still debated; the GC/cGMP/PKG- and AC/cAMP/PKA-mediated smooth muscle hyperpolarization is also controversial\(^{[44-46]}\). In the present experiments, the observation that RLX was able to induce hyperpolarization and that both ODQ and 9CPA prevented this effect actually supports the involvement of GC and AC paths on the RMP modulation.

A remarkable consequence of changes in RMP can be relayed on L-type Ca\(^{2+}\) channels activation, since a greater depolarization is necessary to reach their activation voltage threshold. In this view, it could be hypothesized that the rhythmic spontaneous slow waves of the membrane potential, mainly due to voltage independent channels, only allow a slight number of SMC to reach the voltage threshold for L-type Ca\(^{2+}\) current, useful for contractile activation whereas most of the cells remain relaxed because
their RMP is too negative for the achievement of the electro-mechanical coupling. In fact, the mean positive membrane value of the waves observed in the presence of RLX resulted significantly more negative than that recorded in control condition. Hence, this RLX effect could also have a role in the control of RMP when the SMC reaches depolarized potentials at which L-type Ca\(^{2+}\) channels can be activated: in this case, any reduction of Ca\(^{2+}\) influx through membrane channels can facilitate the setting of negative charges in the inner side of the membrane and thus the hyperpolarization. In addition, whenever the channel can be activated, its activation would be reduced by RLX, since it also modified its voltage-dependence. The consequent reduction of Ca\(^{2+}\) influx caused by RLX fits well with its depressant actions on the mechanical activity, since L-type Ca\(^{2+}\) channels are a chief path through which Ca\(^{2+}\) can enter into the cell and trigger the contractile machinery in intestinal SMCs. Therefore, their modulation represents an effective mechanism playing a role in SMC relaxation. Noteworthy, these voltage-gated Ca\(^{2+}\) channels can be modulated by several signaling systems such as cyclic nucleotides cascades and, even if data about this item are sometimes contradictory\(^{[47]}\), in general it is accepted that cAMP and cGMP inhibit L-type Ca\(^{2+}\) channels. Our results actually support this clue in the ileum: L-type Ca\(^{2+}\) channels resulted inhibited by RLX treatment and either ODQ or 9CPA reduced the effect of RLX, thus indicating that RLX exerts its effects through the activation of both NO/GC/cGMP and AC/cAMP signaling pathways. Since we observed that the blockade of the synthesis of each cyclic nucleotide seems to prevent a full RLX action also through the other pathway, we also suggest a sort of cross-talk mechanism between the two pathways, as previously proposed in vascular\(^{[44]}\) and uterine smooth muscle\(^{[48]}\).

In conclusion, the bulk of the above results indicate that RLX can be considered an efficient intestinal motility modulator since it is able to induce significant changes in smooth muscle mechanical and electrical activity of ileal preparations. In particular, we found that RLX reduces the basal tension and the amplitude of the spontaneous contractions. These effects fit well with the observed decrease of the resting conductance, the membrane hyperpolarization and the diminished Ca\(^{2+}\) influx through L-type channels. All of these actions are exerted by RLX through a dual signaling pathway involving both GC and AC, as reported in other tissues\(^{[10,31]}\).

From a physiological point of view, it could be speculated that the dual signaling pathway may represent a reinforcing and cross-talking (redundant) mechanism for RLX aimed to guarantee its actions and to prolong its modulatory effects in the small intestine. Furthermore, the observation that two pathways are engaged by RLX to cause myorelaxation may create the basis for identifying new therapeutic targets, offering stimulating translational perspectives in the treatment of those intestinal dysmotilities characterized by hypermotility.

In conclusion, this study shows for the first time that RLX exerts its relaxant effects on ileal smooth muscle through the involvement of both GC and AC and suggests a cross-talk between GC/cGMP and AC/cAMP pathways.

**ARTICLE HIGHLIGHTS**

**Background**
Relaxin (RLX) has been reported to modulate gastrointestinal smooth muscle activity in mice through the L-arginine/NO pathway. However, the possibility that the depressant effects of RLX in ileal preparations could involve additional pathways, not fully elucidated yet, was raised. On these grounds, the present study was designed to investigate the signaling pathways involved in the effects of RLX on ileal preparations. To this aim, we performed experiments using a combined mechanical and electrophysiological approach.

**Research frontiers**
The actions of RLX occur through a dual signaling pathway that, from a physiological point of view, might represent a reinforcing and cross-talking mechanism for the hormone aimed to guarantee and to prolong its myorelaxant effects in the small intestine.

**Innovations and breakthroughs**
This study shows, for the first time in ileal preparations, that RLX is able to influence the smooth muscle mechanical and electrophysiological activity through a dual signaling pathway.

**Applications**
The activation of both adenylate cyclase and guanylate cyclase pathways by RLX underlines the physiological importance of the hormone to relax ileal smooth muscle. In this view, it could be speculated that RLX may represent a potential therapeutic tool in those intestinal dysmotilities characterized by hypermotility states.

**Terminology**
The modulation of gastrointestinal smooth muscle activity by hormones may be investigated ‘in vitro’ by recording either the mechanical responses or the electrophysiological properties. In ileal preparations, the hormone RLX has been shown to exert a modulatory role by depressing spontaneous contractions and by influencing the electrophysiological activity.
