PRACTICAL SCENARIO

A meta-analysis examined the effect of the use of daily medium-dose inhaled corticosteroids (ICS) on preventing exacerbations among preschoolers with recurrent wheeze. It summarized the results of 15 randomized clinical trials (RCTs) involving 3,278 individuals that showed that the use of daily ICS, compared with that of placebo, prevented exacerbations by 30% [risk ratio (RR) = 0.70; 95% CI: 0.61-0.79; number needed to treat (NNT) = 9].[1]

COMPARING RISKS

The impact of interventions can be estimated by comparing the incidence of the outcome (e.g., exacerbations) in the experimental group vs. a control group (e.g., placebo) by calculating an outcome ratio or difference across the intervention groups. The typical ratio calculated is the risk in the intervention group over the risk in the control group, designated the risk ratio (RR). In RCTs, the difference in risk between groups is called the absolute risk reduction (ARR), and it represents the proportion of outcomes reduced by the new intervention to the comparison group. Similar estimates can be calculated in observational studies replacing an intervention with the exposure of interest; for example, tobacco smokers compared with nonsmokers when reporting the risk of tobacco-related disease.

A statistic related to the ARR is the NNT, which is important because it provides an estimate of the number of patients that are required to be treated to avoid one additional patient from developing the outcome of interest (Table 1).[2]

The popularity of NNT has increased considerably, although this statistic is not necessarily easier to grasp than the ARR, either by patients or physicians. It is useful to remember that the lower the NNT, the higher the effectiveness of the intervention. In our example, an NNT of 9 is interpreted as follows: 9 children, on average, need to be treated with ICS to prevent 1 additional child from having an exacerbation.

More recently, RCTs also evaluate the impact of adverse events of an intervention by reporting the number needed to harm (NNH) in addition to the NNT. NNH is defined as the average number of individuals that would need to be exposed to a new intervention to produce one additional adverse outcome.

Table 1. Comparing risks and interpreting results across different clinical scenarios. RR: risk ratio; ARR: absolute risk reduction; and NNT: number needed to treat.[2]

| Result                                   | Interpretation                        |
|------------------------------------------|---------------------------------------|
| Low baseline risk (20% risk of death in the control group) |                                       |
| Control group: n = 500; 100 (20%) deaths; Intervention group: n = 500; 75 (15%) deaths |                                       |
| RR                                       | 15%/20% = 0.75 The intervention reduces risk by 25% |
| ARR                                      | 20% − 15% = 5% The intervention reduces risk in 5% |
| NNT                                      | 1%/5% = 20 20 patients need to receive the intervention to prevent 1 death |
| High baseline risk (50% risk of death in the control group) |                                       |
| Control group: n = 500; 250 (50%) deaths; Intervention group: n = 500; 188 (38%) deaths |                                       |
| RR                                       | 38%/50% = 0.75 The intervention reduces risk by 25% |
| ARR                                      | 50% − 38% = 12% The intervention reduces risk in 12% |
| NNT                                      | 1%/12% = 8 8 patients need to receive the intervention to prevent 1 death |
