Abstract

We study the absorption spectra of the yellow excitons in Cu$_2$O in high magnetic fields using polarization-resolved optical absorption measurements with a high frequency resolution. We show that the symmetry of the yellow exciton results in unusual selection rules for the optical absorption of polarized light and that the mixing of ortho- and para- excitons in magnetic field is important. Our calculation of the energies of the yellow exciton series in an arbitrary magnetic field gives an excellent fit to experimental data and allows us to understand the complex structure of excitonic levels and their magnetic field dependence, which resolves the old-standing disagreement between the results of optical absorption and cyclotron resonance measurements.

I. INTRODUCTION

Cuprous oxide Cu$_2$O was the first material in which Wannier-Mott excitons – the particle-hole pairs bound by the Coulomb interaction – were observed. These states give rise to hydrogen-like series of absorption lines in the optical absorption spectrum of Cu$_2$O at the photon energies described by the Rydberg formula, $E_n = E_{\text{gap}} - \frac{\text{Ry}_X}{n^2}$, where $\text{Ry}_X = 98$ meV is the excitonic Rydberg constant and $E_{\text{gap}} = 2.17$ eV is the optical gap. The only exception is the $n = 1$ exciton, which is barely visible because the valence and conduction bands of this material have the same parity. Due to the small size of the $n = 1$ exciton, its energy is strongly affected by the exchange and central cell corrections. The revival of interest in Cu$_2$O was motivated by the search for the Bose-Einstein condensation of the exciton gas. These studies underscored the importance of a quantitative description of excitons in this material. Despite the recent progress, a number of fundamental problems remain, surprisingly, unsolved. For example, there is a significant discrepancy between the effective masses of electrons and holes deduced from the optical measurements and the cyclotron resonance experiments. In addition, a detailed interpretation of the magneto-optical spectra is still lacking. In this paper we address these issues and resolve the discrepancy using the high-resolution measurements of the low-energy magneto-optical absorption spectra of Cu$_2$O combined with the numerical calculations of these spectra in the regime of intermediate magnetic fields.

Optical absorption spectra measured in zero fields give information about the excitonic Rydberg constant and the reduced mass of the electron-hole pair. Further information can be obtained from the splittings of excitonic levels in applied electric and magnetic fields. The magneto-absorption spectra of excitons in Cu$_2$O were extensively studied over the past

TABLE I. Effective masses of electrons $m_e$, holes $m_h$, the dielectric constant $\epsilon$ and an exciton reduced mass $\mu$ obtained in different experiments. The masses are in the units of bare electron mass $m_0$. The last two columns give the $g$-factor of the electrons and holes, respectively.
Because of the large dielectric constant and small effective masses of charge carriers in Cu$_2$O, the exciton radius greatly exceeds that of a hydrogen atom, which amplifies the effects of external electric and magnetic fields on the exciton wave function. For example, the exciton ionization in Cu$_2$O occurs in an electric field of $E = 5$ kV/cm, whereas the characteristic field required to ionize the hydrogen atom is of the order of $E \sim 1000$ kV/cm. Pronounced and fairly complex Zeeman and Stark effects were first observed by Gross and Zakharchenya in magnetic fields up to 2.8 T.

Due to the large radius of the Cu$_2$O excitons, the regime of strong magnetic fields, in which the field-induced level splittings become comparable with the zero field level spacing, can be easily reached in a laboratory (for hydrogen atom such strong fields are only found in neutron stars). For a magnetic field of $H = 30$ T the cyclotron energy is comparable to the binding energy already for the $n = 3$ exciton. For higher levels, the strong-field regime is reached at even lower fields ($\beta_n = \hbar \omega_c / (2Ry_X/n^2) \approx 0.05n^2$, where $\omega_c$ is the cyclotron frequency). However, the interpretation of experimentally measured spectra of exciton states with large $n$ in applied magnetic fields is complicated by the large number of overlapping lines, which makes it difficult to extract exciton parameters from such spectra in a reliable way.

Zhilich et al. studied the oscillations of optical absorption well above the gap in magnetic field up to 10 T. These oscillations originate from the transitions between the Landau levels of electrons and holes. The effective masses of electrons and holes were estimated to be $m_e = 0.61m_0, m_h = 0.84m_0$, where $m_0$ is the bare electron mass. The accuracy of these results was limited by poor energy resolution and available magnetic fields.

At lower energies, in the region of bound excitons, the absorption lines are much sharper and better suitable for extraction of exciton parameters. Sasaki and Kuwabara measured the magnetoabsorption spectrum in static magnetic fields up to 16 T. Kobayashi et al. studied the $n = 2$ and $n = 3$ exciton absorption in pulsed magnetic fields up to 150 T. Seyama et al. measured the spectra in static fields up to 25 T with better spectral resolution. However, the complexity of the spectra with large number of overlapping lines prevented the unambiguous assignment of excitonic levels. In addition, Coulomb interactions between the electron and hole were not taken into account in the analysis of the spectra.

The effective masses obtained from cyclotron resonance experiments: 0.58$m_0$ and
0.69m_0 for light and heavy holes, respectively, and 0.99m_0 for electrons are significantly different from the masses obtained in magnetooptical measurements (see Table I). This disagreement was ascribed to polaronic effects. More recently the value of 0.575m_0 was derived from pulsed cyclotron resonance experiments.

In the attempts to extract the exciton parameters from the spectra measured at high magnetic fields, the Coulomb energy of electron and hole was neglected; an approximation which is justified only for very large magnetic fields and large-n excitons. In works using low excitonic levels the magnetic field was treated perturbatively; an approximation only justified in a limited area of the spectra.

Therefore, the most promising are the levels with n ≤ 5, falling into intermediate field regime β ~ 1. There is no small parameter for a perturbative expansion, and numerical calculations are required to obtain the exciton spectrum.

We performed polarized high spectral resolution optical absorption measurements in static magnetic field up to 32 T and obtained with high accuracy the magnetic field dependence of the exciton energies for n = 2, 3 and 4. The largest part of the spectrum lies in the intermediate-field region, in which the interaction of electrons and holes with the magnetic field is comparable with Coulomb interaction, so that neither of these interactions can be treated perturbatively. We calculated the exciton energies in the intermediate regime numerically and extracted the effective masses and g-factors of the electron and hole by fitting the data. Not only do we get a good agreement between the theory and magnetoabsorption experiments, but the masses that we obtain coincide with those obtained from the cyclotron resonance experiments, thus resolving the long-standing contradiction.

This paper is organized as follows. In Sec. we present the results of magneto-absorption measurements in Cu_2O in static magnetic fields up to 32 T. In Sec. we discuss crystal symmetry and the band structure of Cu_2O. We determine the symmetry of electron and hole wave functions, which allows us to derive the optical selection rules (see Sec. ). Then, in Sec. we calculate the peak positions in the absorption spectrum. The comparison between the experimental and theoretical results is discussed in Sec. VII.
II. EXPERIMENTAL RESULTS

The magneto-absorption of Cu$_2$O has been studied in a Faraday geometry ($\mathbf{H}||\mathbf{k}$) with magnetic fields up to $B = 32$ T at a temperature of $T = 1.2$ K. For the experiments, platelets (thickness 40 $\mu$m) cut and polished from floating zone grown Cu$_2$O single crystals of [100] orientation were placed in a pumped liquid helium bath cryostat. A halogen lamp was used as a light source. Circular polarization was achieved by a combination of a quarter-wavelength plate and a polarizer situated inside the cryostat. The polarized light then was detected with a double monochromator (resolution 0.02 nm) equipped with a LN$_2$ cooled CCD camera. Right ($\sigma^+$) and left ($\sigma^-$) circular polarization of transmitted light was resolved by switching the magnetic field direction: ($\mathbf{H} \uparrow \uparrow \mathbf{k}$) for $\sigma^+$ polarization detection and ($\mathbf{H} \uparrow \downarrow \mathbf{k}$) for $\sigma^-$ polarization detection.

Figure 1 shows the magnetic field dependence of the absorption spectra for some selected field strengths. In the absence of a magnetic field, the absorption spectrum of Cu$_2$O exhibits the well-known hydrogen-like absorption series below the interband transition energy. The spectral resolution of the experiments and the quality of the sample allows the observation of at least 5 exciton peaks of the yellow series ($n=2-6$). Upon applying a magnetic field, the spectra become increasingly more complex; The exciton absorption peaks show a progressive splitting and the continuum above the band gap energy shows a complex magneto-oscillatory spectrum originating from Landau quantization of the unbound electron and hole states.

In order to address the complexity of the spectra, a detailed field dependence of the circular polarized spectra up to $B=32$ T was performed. Figure 2 represents an overview of the optical absorption spectra in a false color representation of the intensity as a function of the photon energy and magnetic field. The left part represents $\sigma^-$ spectra, whereas the right part represents $\sigma^+$ spectra. For the $n = 2$ state, the absorption peak shows a splitting continuous combined Zeeman and Langevin shift upon increasing magnetic field throughout the whole magnetic field range.

The absorption spectrum becomes more complex with the increase of the principal quantum number $n$. In case of Cu$_2$O, only transitions to p-states for each principal quantum number $n$ are dipole-allowed. These states are clearly observed in the absence of a magnetic field. With increasing magnetic field, one can observe other $l$-index (orbital number) states, due to the finite off-diagonal elements induced by the magnetic field. The general
FIG. 1. Magneto-absorption spectra of Cu$_2$O in yellow exciton energy range for different magnetic field strengths. Solid line - left circular polarized spectra; dotted line - right circular polarized spectra. Bath temperature $T = 1.2$ K. The spectra for different fields have been given an offset for clarity.

The energy region in the vicinity and above the band-gap energy is of particular interest (Fig. 2): already at 8T equidistant quasi-Landau levels become visible. Hammura et al.\textsuperscript{115} suggested, that the electron-hole pair undergoes a periodic orbit mainly determined by the

Coulomb potential which is perturbed by the presence of a magnetic potential. Seyama et. al.\textsuperscript{13} considered these levels as a result of frequent level crossing of states with different quantum numbers $n$ and $l$, since the level spacing is comparable with the anti-crossing gaps. As described in the remainder of this paper, the proper description of the complex magnetoabsorption spectrum Fig. 2 follows directly from the gradual transition from exciton to the magneto-exciton behavior without the need for the orbital interference effects as described in\textsuperscript{15}.

III. SYMMETRY OF THE YELLOW EXCITONS

The cuprite Cu$_2$O has a cubic symmetry (space group $Pn\bar{3}m$) with 4 Cu ions in the unit cell (see Fig. 3). The electron can be excited from the highest valence band, formed mostly
FIG. 3. (color online) The unit cell of Cu$_2$O. Oxygen ions in green form a body-centered cubic lattice. The Cu $d$ orbitals (numbered) give the dominant contribution to the upper valence band.  

by the Cu 3$d$ orbitals, to the lowest conduction band, formed by the Cu 4$s$ orbitals. The yellow excitons are then formed by binding the excited electrons and holes with Coulomb interaction.

The symmetries of the electron and hole bands, respectively, $\Gamma_6^{+}$ and $\Gamma_7^{+[2]}$, can be understood as follows. Each Cu$^+$ ion is coordinated by two oxygen ions in the dumbbell configuration, which splits its $d$-shell into two doublets, $(x_i^2 - y_i^2, x_i y_i)$ and $(x_i z_i, y_i z_i)$, and one singlet, $3z_i^2 - r_i^2$. Here the direction of the $z_i$ axis is parallel to the O-Cu-O line passing through the $i$-th Cu ion ($i = 1, 2, 3, 4$) in the unit cell and is different for different Cu sites (see Fig. 3). Since the $3z_i^2 - r_i^2$ state has the highest energy, we assume for simplicity that the upper valence band is formed by these orbitals only.

As the hopping amplitudes between all pairs of the $3z_i^2 - r_i^2$ orbitals on neighboring Cu sites are equal by symmetry, the tight-binding band structure at the $\Gamma$-point consists of the
TABLE II. The transformation rules of the $|X\rangle$, $|Y\rangle$, $|Z\rangle$ states under the operations of $Pn\bar{3}m$ group.

| State | $C_{2z}$ | $C_{3}$ | $m_{x-y}$ | $I$ |
|-------|---------|---------|-----------|-----|
| $|X\rangle$ | $-|X\rangle$ | $|Y\rangle$ | $|Y\rangle$ | $|X\rangle$ |
| $|Y\rangle$ | $-|Y\rangle$ | $|Z\rangle$ | $|X\rangle$ | $|Y\rangle$ |
| $|Z\rangle$ | $+|Z\rangle$ | $|X\rangle$ | $|Z\rangle$ | $|Z\rangle$ |

non-degenerate singlet state,

$$|S\rangle = \frac{1}{2} (|1\rangle + |2\rangle + |3\rangle + |4\rangle)$$

(1)

and the triplet of degenerate states,

\[
\begin{align*}
|X\rangle &= \frac{1}{2} (|+1\rangle - |2\rangle - |3\rangle + |4\rangle), \\
|Y\rangle &= \frac{1}{2} (-|1\rangle + |2\rangle - |3\rangle + |4\rangle), \\
|Z\rangle &= \frac{1}{2} (-|1\rangle - |2\rangle + |3\rangle + |4\rangle),
\end{align*}
\]

(2)

where $|i\rangle$ denotes the $3z_i^2 - r_i^2$ orbital on the $i$-th Cu site. Table II shows the transformation of these three states under the generators of $Pn\bar{3}m$ group: the $\pi$-rotation around the $z$-axis, $C_{2z}$: $(x, y, z) \rightarrow \left(\frac{1}{2} - x, \frac{1}{2} - y, z\right)$, the $\frac{2\pi}{3}$-rotation around the body diagonal of the cube, $C_{3}$: $(x, y, z) \rightarrow (z, x, y)$, the mirror, $m_{x-y}$: $(x, y, z) \rightarrow (y, x, z)$, and inversion $I$: $(x, y, z) \rightarrow (1/2 - x, 1/2 - y, 1/2 - z)$.

As the hopping between nearest-neighbor Cu sites is mediated by oxygen ions, the hopping parameter $t$ of the effective tight-binding model describing the Cu sites only,

$$H = -t \sum_{<i,j>_{\sigma}} \left( c_{i\sigma}^\dagger c_{j\sigma} + c_{j\sigma}^\dagger c_{i\sigma} \right),$$

where the operator $c_{i\sigma}$ annihilates electron in the state $3z_i^2 - r_i^2$ on the site $i$ with the spin projection $\sigma$, is given by $t = \frac{t_{pd}}{\Delta}$, where $t_{pd}$ is the hopping amplitude between the Cu to O sites and $\Delta > 0$ is the charge transfer energy. Since $t > 0$, the states with the energy $+2t$ at the $\Gamma$-point lie higher than the singlet state with the energy $-6t$. The spin-orbit interaction
further splits the six (including the spin degeneracy) states into a doublet

\[
\begin{align*}
|\uparrow\rangle_v &= -\frac{1}{\sqrt{3}} [|X\rangle + i |Y\rangle] |\downarrow\rangle + |Z\rangle |\uparrow\rangle], \\
|\downarrow\rangle_v &= \frac{1}{\sqrt{3}} [(-|X\rangle + i |Y\rangle] |\uparrow\rangle + |Z\rangle |\downarrow\rangle],
\end{align*}
\]

and a quadruplet (here the subscript \(v\) indicates the valence band). The energy of the doublet is higher than the energy of the quadruplet by \(\sim 134 \text{ meV}\). This spin-orbital splitting originates from the virtual admixture of \(x_i z_i\) and \(y_i z_i\) states to the \(3z_i^2 - r_i^2\) state by the spin-orbit coupling on Cu sites. The doublet belongs to the upper valence band, which gives rise to the yellow exciton, while the quadruplet gives rise to the green exciton series. We stress that our \(|X\rangle, |Y\rangle\) and \(|Z\rangle\) states are formed by the \(3z_i^2 - r_i^2\) orbitals of 4 Cu ions in the unit cell and are different from the atomic \(xy, yz,\) and \(zx\) orbitals discussed in Ref. 3.

Using Eq. (3) and Table II, one finds that the valence-band doublet, \(\psi_v = \begin{pmatrix} |\uparrow\rangle_v \\ |\downarrow\rangle_v \end{pmatrix}\), transforms as a \(\Gamma_7^+\) representation:

\[
\begin{align*}
C_2 \psi_v &= e^{-i\frac{\pi}{2}\sigma_z} \psi_v = \begin{pmatrix} -i & 0 \\ 0 & i \end{pmatrix} \psi_v, \\
C_3 \psi_v &= e^{-i\frac{\pi}{\sqrt{3}}(\sigma_x + \sigma_y + \sigma_z)} \psi_v = \frac{1}{2} \begin{pmatrix} 1 - i & -1 - i \\ 1 - i & 1 + i \end{pmatrix} \psi_v, \\
m_{x-y} \psi_v &= \frac{i}{\sqrt{2}} (\sigma_x - \sigma_y) \psi_v = \frac{i}{\sqrt{2}} \begin{pmatrix} 0 & 1 + i \\ 1 - i & 0 \end{pmatrix} \psi_v, \\
I \psi_v &= \psi_v.
\end{align*}
\]

Similarly, the lowest conduction band, formed by the Cu 4s orbitals, splits into a triplet and singlet at the \(\Gamma\)-point with the singlet state having a lower energy. Since the orbital part of the singlet wave function [see Eq. (1)], is invariant under all operations of the space group, the symmetry of the doublet, \(\psi_c = \begin{pmatrix} |\uparrow\rangle_c \\ |\downarrow\rangle_c \end{pmatrix}\), formed by the spin-up and spin-down electron states in the lowest conduction band, is determined by its spin wave function. Thus,
the conduction electron in the yellow exciton has the same transformation properties as the valence electron [see Eq. (4)], except for the opposite sign for the mirror transformation, $m_{x-y}$, and, hence, belongs to $\Gamma^+_6$ representation.

Finally, the conduction electron and the valence hole form ortho- and para-excitons with the total spin, $S$, respectively, 1 and 0. Due to the exchange interaction between the conduction and valence electrons in the $n = 1$ yellow exciton state, the energy of the ortho-exciton is 12meV higher than that of para-exciton. \cite{31,19,22}

IV. SELECTION RULES

Since the valence 3$d$ and conduction 4$s$ bands have the same parity, the excitation of the yellow exciton series is dipole forbidden and results from the electric quadrupole transition. The conduction and valence band doublets, $\psi_c$ and $\psi_v$, transform under the mirror $m_{x-y}$ with opposite signs (see Sec. III), resulting in the “wrong” symmetry of yellow excitons: the paraexciton wave function,

$$|S = 0, S_z = 0\rangle = \frac{1}{\sqrt{2}} (\psi_{c\uparrow}\psi_{v\downarrow} - \psi_{c\downarrow}\psi_{v\uparrow}),$$

is odd under $m_{x-y}$, while the orthoexciton wave function with zero projection of the total spin,

$$|S = 1, S_z = 0\rangle = \frac{1}{\sqrt{2}} (\psi_{c\uparrow}\psi_{v\downarrow} + \psi_{c\downarrow}\psi_{v\uparrow}),$$

is even.

The invariance of the paraexciton wave function $|0, 0\rangle$ under $C_3$ and $C_2$ rotations requires that the amplitude of the photoexcitation of this state has the form,

$$A_{00} \propto \sum_k \varphi_k^* (e \cdot k),$$

(5)

where $k$ is the relative wave vector of the electron-hole pair, $\varphi_k$ is the wave function of the relative motion, discussed in the next section, and $e = e_q\lambda$ is the polarization vector of the photon with the wave vector $q$ and polarization $\lambda$. The scalar product $(e \cdot k)$ is invariant under $m_{x-y}$, while $A_{00}$ must be odd, implying that $A_{00} = 0$, i.e., paraexcitons cannot be excited via the one-photon absorption.
The orthoexciton states $|1, S_z\rangle$ with $S_z = -1, 0, 1$, are excited by the components of the quadrupolar tensor,

$$Q_{ab} \propto \sum_k \varphi_k^* \left( e_a k_b + e_b k_a - \frac{2}{3} \delta_{ab} e \cdot k \right).$$

The excitation amplitudes, invariant under all crystal symmetries, have an obvious form for the Cartesian components of the orthoexciton atomic wave functions, $|x\rangle$, $|y\rangle$, and $|z\rangle$:

\[
\begin{align*}
|1, 1\rangle &= -\frac{1}{\sqrt{2}} (|x\rangle + i |y\rangle), \\
|1, 0\rangle &= |z\rangle, \\
|1, 1\rangle &= \frac{1}{\sqrt{2}} (|x\rangle - i |y\rangle).
\end{align*}
\]

The form of the invariant amplitudes is:

$$A_x \propto Q_{yz},$$

$$A_y \propto Q_{zx},$$

$$A_z \propto Q_{xy},$$

and the proportionality coefficient is the same for all states.

For the Faraday geometry, $q || H$ (and $H || z$),

$$A_x, A_y \propto \sum_k k_z \varphi_k^* \left( \frac{\partial \varphi^*}{\partial z} \right)_{r=0},$$

so that these amplitudes are only nonzero for $m = 0$, where $m$ is the $z$-projection of orbital momentum of the relative motion of the electron-hole pair. Similarly, $A_z$, does not vanish only for $m = \pm 1$ states with nonzero $\left[ \frac{\partial \varphi^*}{\partial x} \mp i \frac{\partial \varphi^*}{\partial y} \right]_{r=0}$. For zero magnetic field the allowed excited states have the orbital momentum $l = 1$ ($p$-states).

In this way we can obtain the following unusual selection rules for orthoexcitons from the yellow series: a photon with the polarization $\lambda = \pm 1 [e_{q, \pm 1} = \frac{1}{\sqrt{2}} (1, \pm i, 0)]$ excites either the state with $S_z = -\lambda$ and $m = 0$, or the state with $S_z = 0$ and $m = -\lambda$. These selection rules are opposite to those for rotationally-invariant systems, where the $z$-component of the total angular momentum is a good quantum number.

V. MOTION OF ELECTRON-HOLE PAIR IN MAGNETIC FIELD

The atomic part of the exciton wave function, discussed in the previous section, remains largely unaffected by an applied magnetic field of 32T, except for the mixing of the paraex-
citon and orthoexciton states. On the other hand, magnetic field has a strong effect on the relative motion of the electron and hole, especially, in highly-excited excitonic states. The problem of finding energies of excitonic states in magnetic field is simplified by the conservation of the total momentum of the electron-hole pair, which makes it equivalent to the problem of hydrogen atom in magnetic field.

The relatively slow motion of electron and hole in the Cu$_2$O excitonic states is, to a good approximation, decoupled from the dynamics of their spins and can be considered separately. The Lagrangian describing this motion is

$$L = \frac{m_e \dot{r}_e^2}{2} + \frac{m_h \dot{r}_h^2}{2} - \frac{e}{c} A(r_e) \cdot \dot{r}_e + \frac{e}{c} A(r_h) \cdot \dot{r}_h + \frac{e^2}{\varepsilon |r_e - r_h|},$$

where $r_e (r_h)$ is the electron (hole) coordinate, $m_e$ and $m_h$ are the electron and hole masses, and $A(r) = \frac{1}{2} [\mathbf{H} \times \mathbf{r}]$ is the vector potential (the electron charge is $-e$).

In the center-of-mass and relative coordinates, $R = \frac{m_e r_e + m_h r_h}{m_e + m_h}$ and $r = r_e - r_h$, the Lagrangian has the form,

$$L = \frac{M \dot{R}^2}{2} + \frac{\mu \dot{r}^2}{2} - \frac{e}{c} (\dot{R} + \frac{\gamma}{2} \dot{r}) \cdot [\mathbf{H} \times \mathbf{r}] + \frac{e^2}{\varepsilon r},$$

where $M = m_e + m_h$ and $\mu = \frac{m_e m_h}{m_e + m_h}$ are, respectively, the total and the reduced mass of the electron-hole pair,

$$\gamma = \frac{m_h - m_e}{m_h + m_e},$$

and the total time derivative $\frac{e}{2c} \frac{d}{dt} (\mathbf{r} \cdot [\mathbf{H} \times \mathbf{R}])$ was omitted from the Lagrangian.

The corresponding Hamiltonian is

$$H = \frac{1}{2M} \left( \mathbf{P} + \frac{\frac{e}{c} [\mathbf{H} \times \mathbf{r}]}{2} \right)^2 + \frac{1}{2\mu} \left( \mathbf{p} + \frac{\frac{e}{c} [\mathbf{H} \times \mathbf{r}]}{2c} \right)^2 - \frac{e^2}{\varepsilon r},$$

where $\mathbf{P} = M \dot{\mathbf{R}} - \frac{e}{c} [\mathbf{H} \times \mathbf{r}]$ and $\mathbf{p} = \mu \dot{\mathbf{r}} - \frac{e}{2c} [\mathbf{H} \times \mathbf{r}]$ are, respectively, the total and relative momenta. The Hamiltonian is independent of the center-of-mass coordinate $\mathbf{R}$, which makes the total momentum $\mathbf{P}$ an integral of motion. Since only the excitons with $\mathbf{P} = 0$ are directly excited in an optical experiment, the Hamiltonian can be written in the form,

$$H = \frac{\mathbf{p}^2}{2\mu} + \frac{e}{2\mu c} \mathbf{L} \cdot (\gamma \mathbf{H}) - \frac{e^2}{\varepsilon r} + \frac{e^2}{8\mu c^2} [\mathbf{H} \times \mathbf{r}]^2,$$

where $\mathbf{L} = [\mathbf{r} \times \mathbf{p}]$ is the orbital momentum. Equation (14) has the form of the Hamiltonian of an electron in the hydrogen atom in a magnetic field $\gamma \mathbf{H}$ and in a parabolic trapping
potential in the plane perpendicular to $\mathbf{H}$ (the last term in Eq. (14) also known as the Langevin or diamagnetic term).

For convenience we choose the cylindrical coordinates with the $z$ axis along the magnetic field, and $\rho = \sqrt{x^2 + y^2}$. The Hamiltonian (14) is invariant under rotations around the direction of magnetic field, therefore $m = \frac{1}{\hbar} L_z$ is a good quantum number. As was discussed in Sec. [IV] only the exciton states with $m = 0, \pm 1$ are excited in the photoabsorption experiment.

The dependence of eigenfunctions on $z$ and $\rho$ was found numerically by solving eigenvalue problem for the Hamiltonian written in the basis of functions,

$$\psi_{mn\rho,nz}(\rho, z) = e^{-(z^2 + \rho^2)/2l^2} \left( \frac{\rho}{l} \right)^{|m|} L_{|m|}^{(m)} \left( \frac{\rho^2}{l^2} \right) H_{nz} \left( \frac{z}{l} \right),$$

where $l = \sqrt{\frac{2\hbar c}{eH}}$ is the magnetic length $l_0 = \sqrt{\frac{\hbar c}{eH}}$ multiplied by $\sqrt{2}$, while $H_{nz}$ and $L_{|m|}^{(m)}$ are, respectively, the Hermite and Laguerre polynomials. In this basis the matrix elements of the Coulomb interaction can be evaluated analytically, which simplifies the calculation of the eigenstates of the Hamiltonian (14).

This method is appropriate in the strong-field limit, where the distance between the Landau levels, $\frac{\hbar c}{\mu c}$, is larger than the exciton Rydberg constant, $\text{Ry}_X = \frac{\mu e^4}{2\varepsilon^2 \hbar^2}$. However, using a rather large basis with $n_\rho \leq 10$ and $n_z \leq 10$, we can extend its applicability up to the physically interesting fields of $\sim 15T$. In the opposite limit of weak fields we diagonalize the Hamiltonian (14) in the basis of the zero-field hydrogen wave functions of the discrete spectrum and truncate the basis at $n = 20$. In both cases we checked that the energies of the levels do not change upon a further increase of the basis dimension. The $H$-dependence of the exciton energies obtained in the two opposite limits matches in the region of intermediate magnetic fields, which allows us to calculate the exciton energies for arbitrary magnetic fields. The dashed lines in figures 5 show the magnetic field dependence of the excitonic levels calculated by numerical diagonalization of the Hamiltonian (14) superimposed on experimental absorption spectra. The red dots indicate the points of a crossover between high- and low-field lines.
VI. FIT TO EXPERIMENTAL DATA

In order to fit the experimental data, it is necessary to take into account the field-dependence of exciton energies resulting from the interaction of the electron and hole spins with the magnetic field $H \parallel z$:

$$\hat{H}_{\text{spin}} = \mu_B H (g_c j^z_c + g_v j^z_v),$$

(16)

where $j^z_c$ and $j^z_v$ are the $z$-components of the angular momenta of the conduction and valence electron forming the exciton and $g_c$ and $g_v$ are respectively the $g$-factors of electrons in the conduction and valence band. The interaction of spins with the magnetic field mixes the ortho $|1,0\rangle$ and para $|0,0\rangle$ states and the corresponding energies are:

$$E_{\pm} = E_0 \pm \sqrt{\left(\frac{\Delta_{o-p}}{2}\right)^2 + \left[\frac{1}{2}(g_c - g_v)\mu_B B\right]^2},$$

where $\Delta_{o-p}$ is the exchange splitting between the ortho and para states in zero field. It is proportional to the square of the enveloping electron-hole wavefunction $\varphi$ at $r = \langle 0 \rangle$, which is only nonzero for $s$-states, whereas electric quadrupole excitation is only allowed to $p$-states [see Eq. (9)]. In fact, existing experimental data on the yellow exciton series shows that the ortho-para splitting is zero for $n > 1$ within the experimental precision.

Therefore, in an applied magnetic field the spin part of exciton wave functions has the form,

$$\psi_+ = \frac{|10\rangle + |00\rangle}{\sqrt{2}} = |\uparrow_c\rangle |\downarrow_v\rangle,$$

$$\psi_- = \frac{|10\rangle - |00\rangle}{\sqrt{2}} = |\downarrow_c\rangle |\uparrow_v\rangle,$$

(17)

which allows us to extract the $g$-factors of electrons in the conduction and valence band (see Sec. VII).

Furthermore, to extract the exciton parameters it is important to take into account that the coupling of excitons to the lattice modifies the shape of the absorption peaks, and shifts the maximum of the absorption away from the position in the rigid lattice. The lineshape can be fitted with the asymmetric Lorenzian,

$$I(\omega) \sim \frac{\hbar \Gamma/2 + 2A(\hbar \omega - E)}{(\hbar \omega - E)^2 + (\hbar \Gamma/2)^2},$$

(18)
where $E$ is the exciton energy in the “rigid” lattice, $\Gamma$ is the exciton-phonon scattering strength and $A$ is the asymmetry parameter.

The fit of the absorption spectrum for the $n = 2, 3$ excitons at various values of magnetic field is shown in Fig. 4, where circles represent the experimental data and the continuous line is a fit by Eq. (18). The linewidth $\Gamma = 2\text{meV}$ for $n = 2$ levels agrees with the results of earlier studies.28

![Absorption Spectrum](image)

**FIG. 4.** (color online) The absorption spectrum for the $n = 2, 3$ exciton (dots) at various values of magnetic field fitted with the sum of asymmetric Lorenzian peaks (solid line) The ‘bare’ exciton energies (see text) are indicated by vertical lines.

The excellent quality of the fit allows us to extract the ‘bare’ exciton energies, indicated by vertical lines. Since the maxima of the absorption spectra are displaced with respect to the bare exciton energies, this procedure enables us to extract the $g$-factors and masses of electron and hole from experimental data in a more reliable way.
VII. DISCUSSION

FIG. 5. (color online) The magnetoabsorption spectra measured in the Faraday geometry, 
$H \parallel |q| (001)$, together with the theoretically calculated magnetic field dependence of the energies 
(dashed lines) for the excitons with [left panel a), set 1] $S_z = -1$ and $m = 0$ and [right panel b), 
set 2] $S_z = 0$ and $m = -1$.

Figure 5 shows the magnetic field and photon energy dependence of the optical absorption 
with the calculated excitonic energies superimposed. In accordance with the selection 
rules, $n \geq 2$ excitons contribute to the optical absorption, forming at zero magnetic field a 
hydrogen-like series $\hbar \omega_n = E_{\text{gap}} - \frac{R_{YX}}{n^2}$ with the optical band gap $E_{\text{gap}} = 2.174$ eV and the 
excitonic Rydberg constant $R_{YX} = 98$ meV. Using $\epsilon = 7.5$ for the dielectric constant, 
we obtain the reduced mass $\mu = 0.41 m_0$ in agreement with Ref. [9].

According to the selection rules derived in Sec. IV, the absorption spectrum for the right 
circularly-polarized light ($\lambda = +1$) is formed by two different sets of states: the states with 
$S_z = -1$ and $m = 0$ (set 1) and the states with $S_z = 0$ and $m = +1$ (set 2). Dashed lines in 
Fig. 5 show the numerically calculated energies of $n = 2, 3, 4$ exciton states in magnetic field 
up to 32T, which belong, respectively, to the sets 1 and 2, superimposed on the experimental 
absorption spectra.

Set 1 corresponds to the absorption of a photon with $\lambda = +1$ and creation of an exciton 
in the state $|1, -1\rangle, m = 0$. The magnetic moment in this state is determined by the atomic 
g-factors of electrons and holes. Since the hole in the upper valence band has $s_z = 1/2$ and
$l_z = -1$, it has zero g-factor since $(l_z + 2s_z) = 0$. The electron wave function is mostly of Cu $s$ character, and since in this case the spin-orbit interaction is not effective, the g-factor should be close to the bare value of 2. Indeed, a good agreement with the experiment is obtained for $g_c = 2.0$ (see Fig. 5b).

The last term in the Hamiltonian Eq. (14) mixes the state $|l, m\rangle$ with the states $|l, m\rangle$ and $|l \pm 2, m\rangle$. This leads to the mixing of $p$ and $f$ states for $n \geq 4$ giving rise to additional lines. In general the line with the main quantum number $n$ splits in magnetic field into $\left\lfloor \frac{n}{2} \right\rfloor$ levels (here $[x]$ denotes the largest integer smaller than $x$).

Set 2 of the absorption lines is produced by the $|1, 0\rangle \pm |0, 0\rangle, m = 1$ excitonic transitions. This set has twice more states, corresponding to $|\uparrow \downarrow v\rangle$ and $|\downarrow \uparrow v\rangle$. The energy shifts of these levels up to the terms linear in the magnetic field are

$$E = 2 \left( \frac{m_0}{m_h} - \frac{m_0}{m_e} \right) \mu_B H m \pm \frac{1}{2} |g_c - g_v| \mu_B H.$$ 

We extracted $m_e = 1.0 m_0$, $m_h = 0.7 m_0$, $|g_c - g_v| = 2.25$ and $g_c + g_v = 2.0$, so that for the atomic g-factors of electrons in the conduction and valence bands we obtain, respectively, $g_c = 2.1$, $g_v = -0.1$ in good agreement with our simple arguments given above. The effective masses coincide with the results of the cyclotron resonance experiment. These values of the parameters result in good agreement between the calculated and the measured spectra.

To conclude, we studied the magneto-absorption spectrum of cuprous oxide in high magnetic fields, calculated excitonic energies for arbitrary field values, and extracted the exciton parameters from the intermediate field region, where the peaks are clearly discernible. Our results suggest that the wide $n = 2$ line is a result of the overlap of two lines with different quantum numbers, resolving a long-standing controversy over the number of excitonic levels in the applied magnetic field. This observation allows us to extract the masses of electrons and holes, which are consistent with the results of cyclotron resonance experiments, and g-factors consistent with the present understanding of the nature of valence and conduction bands of Cu$_2$O.

The binding energy of $n = 1$ exciton is anomalously large (150 meV). The exciton radius of the $n = 1$ exciton (7 Å) is comparable to the lattice constant (4.2 Å), which leads to significant central cell corrections and reduced screening of Coulomb interaction responsible for this anomaly. The corrections to the binding energy of the $n = 2$ level, produced by these mechanisms, are negligible.
