ABSTRACT

Context. Most of the hadronic jet models for quasars (QSOs) and microquasars (MQs) found in literature represent beams of particles (e.g. protons). These particles interact with the matter in the stellar wind of the companion star in the system or with crossing clouds, generating \( \gamma \)-rays via proton-proton processes. Results. We show that formerly used expressions for the particle distributions in the beam as seen by the observer are in error, differences being strongly dependent on the viewing angle. For example, for \( \Gamma = 10 \) (\( \Gamma \) is the Lorentz factor of the blob) and angles larger than \( \sim 20^\circ \), the earlier-used calculation entails an over-prediction (order of magnitude or more) of the proton spectra for \( E > \Gamma mc^2 \), whereas it always over-predicts (two orders of magnitude) the proton spectrum at lower energies, disregarding the viewing angle. Conclusions. All the results for photon and neutrino fluxes in hadronic models in beams that have made use of the earlier calculation are affected. Given that correct \( \gamma \)-ray fluxes will be in almost any case significantly diminished in comparison with published results, and that the time of observations in Cherenkov facilities grows with the square of the flux-reduction factor in a statistically limited result, the possibility of observing hadronic beams is undermined.

Key words. ISM: jets and outflows, astroparticle physics, Gamma-rays: general

1. Introduction

The study of the possible high-energy radiation from QSOs and MQs lacks certainty in one central aspect, the particle composition of the jets. Is the radiation emitted dominantly produced via inverse Compton (synchrotron and/or with external fields) or via proton-proton/proton-photon interactions leading to subsequent meson decay? In the latter case, hadronic jet models have been used in order to assess this possibility. Most of these models represent beams of particles (e.g. protons) linearly propagating in a direction normal to an accretion disc, interacting with the matter in the stellar wind of the companion star in the case of MQs, or with matter in clouds, in the case of quasars. The protons in the beams are usually assumed to be distributed with a power-law which may be cut at high-energies, as would be the case if they are accelerated in Fermi processes within the jet and subject to losses. It is then crucial to have a correct description of the proton distribution as seen by the observer, since the emissivity of \( \gamma \)-ray and neutrino produced by charged and neutral pions make use of cross sections known in that frame. In this paper we present in detail the derivation of a beam particle distribution as seen by the observer and compare it with the earlier-used expression, finding significant differences. Consequences are discussed.

2. Derivation of the particle distribution

In what follows, primed quantities refer to quantities that reside in the jet frame, whereas unprimed quantities are used for those in the observer frame. We consider the Lorentz transformations for energies and momenta

\[ E = \Gamma (E' + \beta p'_\parallel), \quad p'_\parallel = \Gamma (p'_\parallel + \beta E'/c), \quad p'_\perp = \Gamma (p'_\perp - \beta E/c), \]  

where \( p'_\parallel = pc\cos(\theta) \) and \( p'_\perp = pc\sin(\theta) \) are the parallel and perpendicular momentum, respectively. For the relativistic case, \( mc \ll p \) and \( mc^2 \ll E \), the transformation of the energy simplifies to \( E = DE' \), with \( D = 1/\Gamma(1 - \beta \cos(\theta)) \).

The elementary invariants under Lorentz transformations are (see, e.g., Dermer & Menon 2010) the invariant four-volume: \( dxdt = dv \), the invariant phase-space element: \( dp/E = p^2 dpd\Omega/E \to e c d\Omega \), with the final expression applying to photons and extremely relativistic particles, and the invariant phase volume: \( dv = dpd\Omega \), where bold-faces stand for three-dimensional space magnitudes. Because the number \( N \) of particles or photons is invariant, one has that

\[ \frac{dN}{dv} = \frac{1}{p^2} \frac{dN}{dV dpd\Omega} \]
is also invariant. For photons and extremely relativistic particles the last invariant becomes
\[
\frac{1}{c^2} \frac{dN}{dVdEd\Omega}.
\] (3)

Use of the equality \(E^2 = c^2 p^2 + m^2 c^4\), allows to write \(p^2 dp = (pE/c^2) dE\). Use of the latter in Eq. (2) implies that the expression
\[
\frac{1}{pE} \frac{dN}{dVdEd\Omega}
\] (4)
is invariant under Lorentz transformations. Again, for photons and extremely relativistic particles \(pc = E, (= e, in the notation above for this case)\) the last invariant becomes expression (3). We define the differential number density of particles \(n(E, \Omega) \equiv dN/[dVdEd\Omega]\), i.e., the differential number of photons or relativistic particles with dimensionless energy between \(E\) and \(E + dE\) that are directed into differential solid angle interval \(d\Omega\) in the direction \(\Omega\) of some physical volume \(dV\). Because of the invariant (4) and the definition of \(n(E, \Omega)\) we can write that
\[
n(E, \Omega) = n'(E', \Omega') \left( \frac{p}{p'} \right) \left( \frac{E}{E'} \right),
\] (5)
which is valid in general, and
\[
n(E, \Omega) = n'(E', \Omega') \left( \frac{E^2}{E'^2} \right),
\] (6)
which is valid for photons and extremely relativistic particles. Eq. (5) just says that the expression for the distribution function \(f(r, p)\) appearing in kinetic theory of gases, such that the product \(f(r, p) dp dV\) is the number of particles lying in the a given volume element \(dV\) and having momenta in definite intervals \(dp\), is Lorentz-invariant (see e.g., Eq. 10.5 of Landau & Lifshitz 1987). Note that
\[
f(r, p) = \frac{dN}{dV dp} = \frac{dN}{dV p^2 dp d\Omega} = \frac{dN}{(pE/c^2) dV dE d\Omega},
\] (7)
and the invariance of \(f(r, p)\) is that expressed by Eq. (4).

2.1. The extremely relativistic case

In this case the particle density in the jet frame, if it is a power-law defined as
\[
n'(E', \Omega') = (A/4\pi) E'^{-\alpha},
\] (8)
transforms into the observer frame, by virtue of the previous formulæ (3 and 4), as,
\[
n(E, \Omega) = (E/E')^2 n'(E', \Omega') = (A/4\pi) D^2(E/D)^{-\alpha}
\] (9)
\[
= (A/4\pi) E^{-\alpha} D^{2+\alpha}.
\]

2.2. The general case

Using Equations (1) and the one for \(E^2\), it is possible to find that
\[
E/E' = E/[\Gamma(E - \beta cp\cos(\theta))]
\] = \[1/\Gamma \left( 1 - \beta \cos(\theta) \sqrt{1 - m^2 c^4/E^2} \right).
\] (10)

Fig. 1. A power-law spectrum of protons in a beam as seen by the observer for different values of viewing angles, and an example of Lorentz factor and slope (solid lines). The grey-dashed lines stand for the earlier derivation results for the same parameters (see [2,4]).

In addition, using the Lorentz transformation for momenta (Eq. 1 and the fact that \(p_\perp = p\sin(\theta) = p'\), one has
\[
p'^2 = p^2 \sin^2(\theta) + \Gamma^2 (p\cos(\theta) - \beta E/c^2)
\] = \[p^2 \left[ \sin^2(\theta) + \Gamma^2 (\cos(\theta) - \beta E/\sqrt{E^2 - m^2 c^4}) \right]^2.\] (11)

Using the latter expression to get \(p/p'\) and inserting this into Eq. (5), together with Eq. (8) and Eq. (10) we get,
\[
n(E, \Omega) = \frac{A}{4\pi} \times \left[ \frac{\Gamma^{-\alpha-1} E^{-\alpha} (1 - \beta \cos(\theta) \sqrt{1 - m^2 c^4/E^2})^{-\alpha-1}}{\sin^2(\theta) + \Gamma^2 (\cos(\theta) - \frac{\beta}{\sqrt{1 - m^2 c^4/E^2}})^2} \right]^{1/2}.
\] (12)

Note that in the limit, when \(mc^2 \ll E\), the latter expression reduces to \((A/4\pi) E^{-\alpha} D^{2+\alpha}\). To prove the latter we use that \((\sin^2(\theta) + \Gamma^2 (\cos(\theta) - \beta E/c)^2)^{1/2} = 1/D\), which can be established by squaring both sides, and summing and subtracting \(\Gamma^2 \sin^2(\theta) + \Gamma^2 \beta^2 \cos^2(\theta)\) on the left hand side, with the additional use of the definition of \(\Gamma^2 = 1/[1 - \beta^2]\). Note also that we are not assuming a specific jet composition, thus it is a general result for any kind of particle distributions. Figure 1 shows the resulting expression (12) for a power-law spectrum of protons in a beam as seen by the observer, for different values of viewing angles, and an example of Lorentz factor and slope (solid lines). Note that for high energies, when \(E > \Gamma mc^2\), \(n(E, \Omega)\) is a power-law distribution, as the original primed one, albeit it presents a different behavior for lower values of \(E\).

2.3. A power-law with an exponential cutoff

We shall briefly also consider the case in which the intrinsic particle distribution in the beam is a power-law with an exponential cutoff. This would be a natural resulting consequence of particles being subject to losses on the same
site where they are accelerated. As such, the cutoff appears in the primed referenced frame, where
\[ n'(E', \Omega') = (A/4\pi)E'^{-\alpha} \exp(-E'/E_{\text{cut}}). \]  
(13)

Note that \( E_{\text{cut}} \) should be fixed in the beam frame, where acceleration and losses are supposed to occur, but once fixed it is at all effects a number, and it is not subject to Lorentz transformations. However, the energy variable in the exponential function is. The result is

\[ n(E, \Omega) = \frac{A}{4\pi} \Gamma^{-\alpha-1} E^{-\alpha} \left( 1 - \beta \cos(\theta) \sqrt{1 - m^2 c^4/E^2} \right)^{-\alpha-1} \left( \sin^2(\theta) + \Gamma^2 \left( \cos(\theta) - \frac{\beta}{\sqrt{1 - m^2 c^4/E^2}} \right)^2 \right)^{1/2} \exp \left( -\frac{\Gamma E}{E_{\text{cut}}} \left( 1 - \beta \cos(\theta) \sqrt{1 - m^2 c^4/E^2} \right) \right). \]

When \( mc^2 \ll E \), the exponential cutoff \( \exp(-E'/E_{\text{cut}}) \) gets transformed into \( \exp(-E/DE_{\text{cut}}) \), with \( D \) being the bulk Doppler factor.

2.4. Comparison with Purmohammad & Samimi (2001)

Purmohammad and Samimi (PS01) states that the isotropic particle distribution transformed from the jet into the observer frame results in (in this subsection and to avoid confusion we label their expressions with a *)

\[ n_*(E, \Omega) = \frac{A}{4\pi} \Gamma^{-\alpha+1} E^{-\alpha} \times \left( 1 - \beta \cos(\theta) \sqrt{1 - m^2 c^4/E^2} \right)^{-\alpha} \left( \sin^2(\theta) + \Gamma^2 \left( \cos(\theta) - \frac{\beta}{\sqrt{1 - m^2 c^4/E^2}} \right)^2 \right)^{1/2}. \]

Purmohammad and Samimi’s (2001) paper does not provide a derivation of their Eq. (3), quoted above as (15), but earlier private communication with one of us was sufficient to reconstruct it. The steps are the following. They start by assuming conservation of particles in the form

\[ n_*(E, \Omega) dV d\Omega dE = n'_*(E', \Omega') dV' d\Omega' dE', \]  
(16)

thus one has

\[ n_*(E, \Omega) = n'_*(E'(E, \theta), \Omega'(E, \theta)) \frac{dV'}{dV} \frac{d\Omega'}{d\Omega} \frac{dE'}{dE}. \]  
(17)

From the Lorentz-invariance of the phase-space element \( dp/dE \), the invariance of \( pd\Omega dE \) can also be proved. Then, one can write that

\[ \frac{d}{dE'} \frac{dV'}{d\Omega'} = \frac{d}{dE} \frac{dV}{d\Omega}. \]  
(18)

Using the expressions derived above for \( p/p' \), and the equality \( dV' = \Gamma dV \), into (17), one gets

\[ n_*(E, \Omega) = \frac{\Gamma(A/4\pi)E^{-\alpha}}{\sqrt{\sin^2(\theta) + \Gamma^2(\cos(\theta) - \beta E/\sqrt{E^2 - m^2 c^4})^2}}. \]

(19)

From here, after replacing in the numerator \( E' = \Gamma(E - \beta \rho c \cos(\theta)) = \Gamma(E - \beta \cos(\theta) \sqrt{E^2 - m^2 c^4}) \), the expression (15) immediately follows.

Formally, one can say that there is a problem hidden in Eq. (16), from where the rest of the derivation follows. The invariant phase variable is not \( dV d\Omega dE \) but rather \( p^2 dV d\Omega d\rho \). To avoid inconsistencies, invariants (from where to derive transformation laws) should be written as operations over individually invariant factors, e.g., \( dN \) over \( dv \), rather than from identities (which is what one obtains replacing the definition of \( n \) and \( n' \) in Eq. (16)). However, the latter can also yield to the correct result too if care is exercised. In practice, then, the problem with the prior derivation is in the use of the equality \( dV' = \Gamma dV \). The latter equation implies that \( dV' \) is the proper volume \( dV_0 \); which is clearly incorrect, given the fact that the momentum, \( p' \), of the particles in that volume is not zero. Only for the proper volume the referred equality is true (see, e.g., eq. 4.6 of Landau & Lifshitz 1987). To clarify this issue, let us introduce, in addition of the two reference systems (observer and beam), another frame \( K_0 \) in which the particles with the given momentum are at rest. The proper volume \( dV_0 \) of the element occupied by the particles is defined relative to this system. The velocities of the primed and unprimed systems relative to the system \( K_0 \) coincide by definition with the velocities \( v \) and \( v' \) which these particles have in the systems of the observer and the beam, respectively. Thus, we can write

\[ dV = dV_0 \sqrt{1 - v^2/c^2}, \quad dV' = dV_0 \sqrt{1 - v'^2/c^2} \]

(20)

from which one can write

\[ \frac{dV}{dV'} = \sqrt{1 - v'^2/c^2} = \frac{E'}{E}. \]  
(21)

If we use Eqs. (18) and (21) in Eq. (16), the latter transforms back into the expression of the invariant quantity \( 1/(pE) \times dN/(dV d\Omega d\rho) \) and Eq. (5) follows.

The difference between expression (15) and our Eq. (12) is important. Diving it one by another we obtain

\[ n(E, \Omega) / n_*(E, \Omega) = \Gamma^{-2}(1 - \beta \cos(\theta) \sqrt{1 - m^2 c^4/E^2})^{-1} \]

(22)

which is a non-trivially dependent function of \( \Gamma, E, \) and \( \theta \). However, note that it is not a function of \( \alpha \). In the extremely relativistic case; \( mc^2 \ll E \) one notices a factor \( D/\Gamma \) of difference. Put otherwise, in the stated asymptotic regime, the ratio expressed by Eq. (22) reduces to \( n(E, \Omega)/n_*(E, \Omega) = \Gamma^{-2}(1 - \cos(\theta) \sqrt{1 - 1/\Gamma^2})^{-1} \), which is only a function of \( \Gamma \) and \( \theta \). One can see that in the case of \( \theta = 0^\circ \), \( n(E, \Omega)/n_*(E, \Omega) \to 2 \) for growing \( \Gamma \). For other values of \( \theta \), this 2D function quickly fall off. We plot the comparison between our derivation and that by PS01 in Figure 2 both as a function of viewing angle \( \theta \) (for fixed \( \Gamma = 10^0 \)) and bulk Lorentz factor \( \Gamma \) (for \( \theta = 20^\circ \)). We see that the differences amounts from a factor of \( \sim 2 \) in the case of directly-pointing beams of blazars and microblazars (of very low \( \theta \), in our example, 0.6°) to one order of magnitude at least for the more common cases of moderate inclinations (e.g., for 20°; with the difference being significantly larger for larger inclinations). Note that as soon as \( \theta \) is larger than \( \sim 5^\circ \), the proton spectrum in the beam increasingly undershoots PS01’s calculation; this leads to an analogous correction of previously calculated \( \gamma \)-ray and
neutrino emission (typically by more than one order of magnitude) in all cases in which the expression (15) was used. Note also that in the low energy decline PS01’s calculation always overestimates significantly (by about two orders of magnitude) the correct yield of the proton spectrum (see Fig. 1 at proton energies between 1 and 10 GeV).

3. Discussion

The proton beam model presented by PS01 gives an expression for a power-law proton spectrum in a beam, as seen by the observer. We have demonstrated that this expression is incorrect, since it is not complying with relativistic invariants. We have derived the correct transformation from the jet frame particle density to the observer’s, which strictly obeys these Lorentz invariance constraints. By comparing our result with PS01, we noticed that differences are strongly dependent on the viewing angle. For many cases, PS01 calculation entails a significant over-prediction (order of magnitude) of the proton spectra for $E > \Gamma mc^2$, whereas it always significantly over-predicts (two orders of magnitude) the proton spectrum at lower energies, disregarding the viewing angle. The $\gamma$-ray luminosity is related to the particle density through the corresponding emissivity of the processes by which the particles interact. For instance, the charged and neutral pion decay channels is the most effective yield of photons and neutrinos in many situations, and its emissivity is directly proportional to the particle density $n(E, \Omega)$. A large number of publications relying on the calculation by P Liamad & Samimi (2001) for estimating $\gamma$-ray and neutrino emission yields in hadronic beam scenarios are thus affected in the way described above.

One particular example can be seen in the hadronic MQ case (Romero et al. 2003) and their applications (e.g., Romero et al. 2005, Orellana et al. 2007, Reynoso et al. 2008). These are all affected on the light of our results. MQs can have $\Gamma \sim 2$, but $\theta$-values above $10^0$ are typical. MQs can precess, as is the case of SS433, where $\theta$ can change even up to $20^0$ around an already large mean viewing angle.

Only a small part of the $\gamma$-ray AGNs belong to the nonblazar class. The majority among those associated with radio sources possess relatively large core dominance (Abdo et al. 2010), indicating that their viewing angle is likely not large. Assuming $\theta < 20^0$, if $\Gamma < 10$, PS01 deviation is not more than a factor of $\sim 6$ (at $E > mc^2$). For the average blazar with $\Gamma = 10$ and $\theta < 10^0$ the difference is a factor of $\sim 2$. However, it has been argued that during

---

1 Note that the eq. (2) in the latter paper, has a missing square in the denominator factor $(\cos(\theta) - \beta E/\sqrt{(E^2 - m^2 c^4)})$. This typo has been adopted in several of the papers quoting Romero et al (2003).
extreme TeV flaring events of some blazars (e.g. Mkn 501, PKS 2155-304), Lorentz factors greater than $\Gamma \sim 50$ are required (e.g. Begelman et al. 2008). If the viewing angle remains at $\theta \sim 1/\Gamma_{\text{quiet}} \sim 1/10 \sim 5.7^\circ$ during such events, PS01 formulation error can grow to more than an order of magnitude. Furthermore, a few radio galaxies with large viewing angles are also detected at $\gamma$-ray energies: M87 with viewing angle $\theta < \sim 40^\circ$, and Cen A where estimates for the viewing angle range from $15^\circ$ to $80^\circ$. These radio galaxies have been already modeled with the PS01 derivation (e.g., Reynoso et al. 2010). Here, the difference between the PS01 formula and ours can reach up to a factor 20 for $\Gamma$ not larger than 5.

Finally, we note that models designed to predict future detections of large-viewing angle sources with higher sensitivity instruments than currently available will greatly overpredict the number of sources if the PS01 formula is used. Similarly, a model for an AGN which overestimates the $\gamma$-ray flux could make wrong associations of unidentified $\gamma$-ray sources. Given that $\gamma$-ray fluxes will be in many cases diminished, and that the time of observations in Cherenkov facilities grows with the square of the flux-reduction factor, the likelihood of observing hadronic beams is undermined.
