By using Gutzwiller projected fermionic wave functions and variational Monte Carlo technique, we study the spin-1/2 Heisenberg model with the first-neighbor (J\textsubscript{1}), second-neighbor (J\textsubscript{2}), and additional scalar chiral interaction J\textsubscript{3}S\textsubscript{i} \cdot (S\textsubscript{j} \times S\textsubscript{k}) on the triangular lattice. In the non-magnetic phase of the J\textsubscript{1} - J\textsubscript{2} triangular model with 0.08 \lesssim J\textsubscript{2}/J\textsubscript{1} \lesssim 0.16, recent density-matrix renormalization group (DMRG) studies [Zhu and White, Phys. Rev. B 92, 041105 (2015); Hu, Gong, Zhu, and Sheng, Phys. Rev. B 92, 140403 (2015)] find a possible gapped spin liquid with the signal of a competition between a chiral and a Z\textsubscript{2} spin liquid. Motivated by the DMRG results, we consider the chiral interaction J\textsubscript{3}S\textsubscript{i} \cdot (S\textsubscript{j} \times S\textsubscript{k}) as a perturbation for this non-magnetic phase. We find that with growing J\textsubscript{3}, the gapless U(1) Dirac spin liquid, which has the best variational energy for J\textsubscript{3} = 0, exhibits the energy instability towards a gapped spin liquid with non-trivial magnetic fluxes and nonzero chiral order. We calculate topological Chern number and ground-state degeneracy, both of which identify this flux state as the chiral spin liquid with fractionalized Chern number C = 1/2 and two-fold topological degeneracy. Our results indicate a positive direction to stabilize a chiral spin liquid near the non-magnetic phase of the J\textsubscript{1} - J\textsubscript{2} triangular model.

I. INTRODUCTION

Quantum spin liquid is one kind of long-range entangled states without breaking neither spin rotational nor lattice translational symmetries even at zero temperature\textsuperscript{1,2}. The physics of spin liquid has been playing an essential role to understand strongly correlated systems and unconventional superconductivity\textsuperscript{3,4}. The emergent topological order\textsuperscript{5-7} and fractionalized quasiparticles\textsuperscript{8-10} of spin liquid have wide applications on quantum computations and quantum communications\textsuperscript{11}. In experiment, one of the best candidates to realize spin liquid is frustrated antiferromagnetic material. A natural way to form geometric frustration is to have the corner-sharing triangle and the face-sharing triangle structures on lattice.

The simplest lattice which is constructed from corner-sharing triangles is the kagomé lattice. At experimental side, the most promising materials to realize spin liquid on kagomé lattice are the spin-1/2 antiferromagnets herbertsmithite and kapellasite\textsuperscript{12-17}. Theoretically, density-matrix renormalization group (DMRG) studies consistently find a gapped spin liquid in the spin-1/2 kagomé Heisenberg model with the nearest-neighbor (NN) interactions\textsuperscript{18-20}. However, the variational studies based on projected fermionic parton wave functions favor a gapless U(1) Dirac spin liquid (DSL) with competing ground-state energy\textsuperscript{21-24}. Near the NN model, a robust chiral spin liquid (CSL)\textsuperscript{25-28} is unambiguously established by introducing second- and third-neighbor couplings or chiral interaction\textsuperscript{29-35}. This CSL spontaneously breaks time-reversal symmetry (TRS) and is identified as the ν = 1/2 bosonic fractional quantum Hall state.

On the other hand, the typical system with face-sharing triangles is the simple spin-1/2 triangular lattice system. The NN Heisenberg antiferromagnetic model on the triangular lattice is the first candidate proposed to realize a spin liquid\textsuperscript{36}; however, a 120° antiferromagnetic order is found in the subsequent studies\textsuperscript{37-40}. Although spin liquid does not exist in the NN model, both experimental and theoretical studies find that the additional interactions may open a new route for realizing such states. In the organic weak Mott insulators with triangular lattice structure such as κ-(ET)$_2$Cu$_2$(CN)$_3$ and EtMgSb[Pd(dmit)$_2$]$_2$\textsuperscript{41-46}, no magnetic order is observed at the temperature much lower than the interaction energy scale. The spin liquid behaviors are explained by a gapless spin Bose metal state realized in a triangular model with four-site ring-exchange interactions\textsuperscript{47-50}. The spatial anisotropic triangular model with the NN couplings J\textsubscript{1} - J\textsubscript{1}' has also been studied extensively to find a possible spin liquid state at the neighbor of the spin spiral phase\textsuperscript{51-55}. Recently, different theoretical studies consistently find a non-magnetic phase in the J\textsubscript{1} - J\textsubscript{2} triangular Heisenberg model, which is sandwiched between the 120° and the stripe magnetic order phases for 0.08 \lesssim J\textsubscript{2}/J\textsubscript{1} \lesssim 0.15\textsuperscript{56-64}. DMRG results suggest a gapped spin liquid for this non-magnetic phase\textsuperscript{56,61}. However, the finite-size DMRG calculations find numerical signals for both CSL and Z\textsubscript{2} spin liquid\textsuperscript{61}, which may imply strong finite-size effects; therefore, the system has difficulty to settle into one state. On the other hand, recent variational Monte Carlo studies\textsuperscript{64} find that the gapless U(1) DSL hosts the best variational energy than the various Z\textsubscript{2} spin liquids in parton constructions\textsuperscript{65,66}. Now, the understanding of this non-magnetic phase in triangular model is in the similar situation as the NN kagomé model, both of which exhibit various candidate ground
states with close energies. Inspired by the CSL signals in the triangular model and the emerging CSL in kagomé model by considering different perturbations, we address the issue that whether a CSL might also be stabilized by introducing further perturbations in the $J_1 - J_2$ triangular model.

Motivated by this question, we use the variational Monte Carlo (VMC) calculations based on the flux state of fermionic representation to study the $J_1 - J'_1 - J_2$ triangular Heisenberg model with additional TRS breaking chiral interactions. The model Hamiltonian is defined as

\[ H = J_1 \sum_{\langle ij \rangle_{\text{horizontal}}} S_i \cdot S_j + J'_1 \sum_{\langle ij \rangle_{\text{zigzag}}} S_i \cdot S_j + J_2 \sum_{\langle \langle ij \rangle \rangle} S_i \cdot S_j + J_X \sum_{\Delta / \nabla} (S_i \times S_j), \]

where $J_1$ and $J'_1$ are the horizontal and zigzag NN couplings, respectively (see Fig. 1(a)). We set $J_1 = 1.0$ as energy scale, and focus on the phase regime with $0.96 \leq J'_1 \leq 1.04$ and $0 \leq J_2 \leq 0.15$. The chiral couplings $J_X$ have the same magnitude in each triangle (up triangle $\Delta$ and down triangle $\nabla$) as shown in Fig. 1(a), and the sites $i$, $j$, and $k$ follow the clockwise order in all triangles. In recent VMC calculations by Zhang, et al., some topological features of the spin liquids constructed based on fermionic flux states have been obtained. In particular, the VMC studies find the CSL in the extended kagomé model by showing the ground-state degeneracy and topological Chern number. In our calculations, we will follow these techniques.

Through our VMC calculations, we find that while the 120° antiferromagnetic order vanishes at a finite chiral coupling $J_X$ for $J_2 \lesssim 0.08$, the gapless U(1) DSL in the non-magnetic phase $0.08 \lesssim J_2 \lesssim 0.15$ has the instability towards a CSL as soon as we turn on the $J_X$ term. This CSL has a quantized topological Chern number $C = 1/2$ and two-fold topological degenerate ground states, which characterize the CSL as the $\nu = 1/2$ fractional quantum Hall state. We also study the relation between the chiral order and the lattice anisotropy of the $J_1$ coupling in the CSL phase regime. We find the consistent behaviors with the DMRG results that some spin coupling anisotropy may enhance the robustness of the CSL. Our VMC results indicate a positive direction to stabilize a CSL near the non-magnetic phase in the $J_1 - J_2$ triangular Heisenberg model.

II. VARIATIONAL WAVE FUNCTIONS

Following one of the novel ways to construct spin liquid states beyond the mean-field level, we introduce the projected fermionic wave functions for our variational calculations. In this representation, spin operator $S_i$ is expressed using the spinon operators as $S_i = \frac{1}{2} c_i^{\dagger} \sigma_{\alpha\beta} c_{i,\alpha}^{\dagger} c_{i,\beta}$, where $\sigma = (\sigma^x, \sigma^y, \sigma^z)$ is the Pauli matrices and $c_{i,\sigma}^{\dagger}$ creates (annihilates) an electron with spin $\sigma$ at site $i$. Therefore, the Hamiltonian Eq. (1) could be represented using the fermionic operators, and the Gutzwiller projector $P_G = \prod_i (1 - n_i c_i c_i^{\dagger})$ is introduced to enforce no double occupation on each site. For the variational calculations, we define the variational wave function as

\[ |\Psi_v\rangle = J_s P_G |\Psi_0\rangle, \]

where $J_s = \exp(1/2 \sum_{ij} v_{ij} S_i^z S_j^z)$ is the spin Jastrow factor describing magnetic orders. The variational parameters $v_{ij}$ depend on the distance between sites $i$ and $j$. $|\Psi_0\rangle$ is an uncorrelated ground state of mean-field Hamiltonian. In the previous VMC calculations of the $J_1 - J_2$ Heisenberg model, the $Z_2$ spin liquids have the higher energy than the gapless U(1) DSL in the intermediate $J_2$ regime (0.08 $\lesssim J_2 \lesssim 0.16$); thus, we consider the mean-field Hamiltonian only with the NN hopping term consistent with the DSL,

\[ \mathcal{H}_{\text{MF}} = \sum_{\langle i,j \rangle, \sigma} t_{ij} c_{i,\sigma}^{\dagger} c_{j,\sigma} + h.c. \]

As shown in Fig. 1(b), the solid (dashed) bonds denote the positive (negative) signs of $t_{ij}$, which define a magnetic flux $\Phi = \pi$ crossing down triangles and $\Phi = 0$ crossing up triangles (or opposite). For the NN hopping, $t_{ij} = t_1$. Thus, the unit cell is doubled in this DSL. In our study considering bond anisotropy and CSL, we allow the anisotropy of the NN hopping $t_{ij}$ and $t'_{ij}$ with both real and imaginary parts, i.e., $t_{ij} = |t_{ij}| e^{i \phi_{ij}}$. In Fig. 1(b), we show the $\text{Ansatz}$ of the variational wave function. Since the requirement of $t_{ij}^* = t_{ij}$, we define the orientation of the hopping terms in this way: for the hopping from $j$ to $i$, $t_{ij}$ ($t'_{ij}$) has the direction (opposite direction) along the arrow shown in Fig. 1(b). Here, we choose the definition that the up triangles have the fluxes $\theta_1 = \phi_1 + 2\phi_1'$, and the down triangles have the fluxes $\theta_2 = \pi - \theta_1$. Such
a state can be denoted as $[\theta_1, \pi - \theta_1]$. Thus, using this symbol, the U(1) DSL has the fluxes $[0, \pi]$, and the wave functions with non-zero $\theta_1$ describe the states with spin chirality\textsuperscript{5}. In Ref. 64, the U(1) DSL has competitive variational energy in the non-magnetic phase of the $J_1 - J_2$ model.

We will also consider the effect of $J_\chi$ to the $120^\circ$ Néel order for $J_2 \lesssim 0.08$. In this case, we define the magnetic states as

$$\mathcal{H}_{\text{MAG}} = \sum_{\langle i,j \rangle, \sigma} (t_{ij} c_{i,\sigma}^\dagger c_{j,\sigma} + h.c.) + h \sum_{i} \mathbf{M}_i \cdot \mathbf{S}_i, \quad (4)$$

where the magnetic order is described by variational parameter $h$ and unit vector $\mathbf{M}_i$. The magnetic long-range order is directly related to a non-zero $h$. For describing the $120^\circ$ Néel state, we set $\mathbf{M}_i = (\cos(r_i \cdot \mathbf{q} + \eta_i), \sin(r_i \cdot \mathbf{q} + \eta_i), 0)$ ($\mathbf{q}$ is the pitch vector and $\eta_i$ is the phase shift for the sites within the same unit cell) with $\mathbf{q} = (4\pi/3, 0)$. For the unit vector $\mathbf{M}_i$ in the XY plane, the spin Jastrow factor $J_s = \exp(1/2 \sum_{i,j} v_{ij} S_i^z S_j^z)$ correctly describes spin fluctuations around the classical state in the XY plane\textsuperscript{72}.

In this paper we study the competitions among the $120^\circ$ Néel state, the gapless U(1) DSL, and the gapped CSL. We perform variational calculations at half filling on toric clusters with $L \times L$ sites under the periodic/antiperiodic boundary conditions (PBC/APBC). In order to find the energetically favored state, we use the stochastic reconfiguration (SR) optimization method\textsuperscript{73} to optimize the variational parameters.

**Figure 2:** (Color online) Finite-size scaling of the magnetic order variational parameter $h$ for $J_2 = 0$ and 0.05 with $J_1 = J_1'$. We use the $L \times L$ toric clusters with PBC at $L = 6, 12, 18, 24, 30$. Quadratic fittings are used for all the data.

**Figure 3:** (Color online) The variational Monte Carlo optimizations of the flux $\theta_1 = 3 \arctan(Im(t_1)/Re(t_1))$ are shown for $J_2 = 0.1$ and $J_\chi = 0.05$ on $L = 6$ (a) and 12 (b) clusters. Different initial values $\theta_1 = 0.32$ ($Im(t_1) = 0.107$) and 0 are chosen.

### III. COMPETITION BETWEEN MAGNETIC AND CHIRAL ORDERS

First of all, we study the competition between the magnetic and chiral orders for $J_2 \lesssim 0.08$ with $J_1 = J_1'$. When $J_\chi = 0$, the system has the $120^\circ$ Néel order. When $J_\chi$ is much larger than $J_1$ coupling, the classical spin analyses show that the system would become a non-coplanar tetrahedral state with four sublattices, where the spins of four sublattices point toward the corners of a tetrahedron\textsuperscript{74}. Therefore, with growing $J_\chi$, we expect the system to transit either directly from the $120^\circ$ Néel order to the tetrahedral phase, or through an intermediate phase. Interestingly, the CSL discovered in the kagomé model emerges between a $120^\circ$ Néel phase and the non-coplanar cubic phase\textsuperscript{32}. In our present studies, we do not include the variational wave function of the tetrahedral state. Thus, we only consider the vanishing of the $120^\circ$ Néel order with the increase of $J_\chi$ (we expect further studies using unbiased methods to investigate the phase transition between the $120^\circ$ Néel and the tetrahedral phases in the future work).

In our variational calculations for $J_2 \lesssim 0.08$, we start from the wave function Eq. (4) and optimize the parameter $h$ and Jastrow factor $v_{ij}$. $h = 0$ describes the vanished Néel order. We study the lattice with $L = 6, 12, 18, 24, 30$, where the $120^\circ$ Néel order is not frustrated by boundary conditions. In Fig. 2, we show the variational parameter $h$ of magnetic order for $J_2 = 0$ and 0.05 with $J_\chi$ on different clusters. For both $J_2$ couplings with small $J_\chi$, the variational parameter $h$ decreases quite slowly with increasing system sizes and smoothly extrapolates to a finite value in the thermodynamic limit. When $J_\chi$ is large enough ($J_\chi \gtrsim 0.1$), the magnetic order parameter $h$ decreases sharply and scales to vanishing when $L \to \infty$. Our results clearly indicate that there is a phase transition with vanished $120^\circ$ Néel order.
order at a finite $J_X$.

IV. CHIRAL SPIN LIQUID EMERGING NEAR THE GAPLESS DIRAC SPIN LIQUID

In this section, we study the possible CSL near the gapless $U(1)$ DSL. We start from the non-magnetic variational wave function Eq. (3) without magnetic term ($h = 0$) and spin Jastrow factor ($v_{ij} = 0$). Thus, the variational parameters are the imaginary part of $t_1$ and both real and imaginary parts of $t_1'$. We will focus our studies for $J_2 = 0.1$.

A. Isotropic system with $J_1 = J_1'$

1. Optimization and measurement of local order parameters

For the isotropic system with $J_1 = J_1'$, we have $t_1 = t_1'$, and the only variational parameter is the imaginary part of the NN hopping. Before discussing the results, we demonstrate the good convergence of our calculations. In Fig. 3, we show the optimization of $\theta_1$ for $J_2 = 0.1$, $J_X = 0.05$ on the $6 \times 6$ and $12 \times 12$ clusters. We obtain the converged $\theta_1$ after optimization, which are found to be independent of initial values.

To study the CSL, we optimize the variational wave function for different $J_X$ on different system size with $L$ up to $L = 30$. On the $L = 6$ and $L = 12$ clusters, we study the system with $J_X$ up to 0.3. As shown in Fig. 4, the optimized flux $\theta_1$ increases with the growing $J_X$. For $J_X = 0.02, 0.05, 0.1$, we study the larger clusters, which give the optimized $\theta_1$ that almost do not change with increasing system size. In the inset of Fig. 4, we also show the finite-size scaling of the ground-state energy for small $J_X$, which support the good convergence of the calculations with system size.

With the optimized finite variational parameter $\theta_1$, we expect non-zero chiral order of the optimized wave function, which can be measured through the three spins scalar chirality in each triangle as:

$$\langle \chi \rangle = \langle S_1 \cdot (S_2 \times S_3) \rangle. \quad (5)$$

In our calculations, we find that the chiral order parameter $\langle \chi \rangle$ of the up and down triangles are within the error bar. In Fig. 5, we show $\langle \chi \rangle$ as a function of the chiral coupling $J_X$ on different clusters up to $L = 30$, which grows continuously with increasing $J_X$. The finite-size scaling in the inset of Fig. 5 clearly demonstrates the non-zero chirality in the thermodynamic limit.

2. Topological properties

In order to characterize the non-trivial topological properties of the chiral state, we calculate the topological Chern number and the ground state degeneracy.

In our calculations, the topological Chern number is computed as the integral over the Berry curvature $F(\Theta_1, \Theta_2)$ in boundary phase space $^{76-78}$

$$C = \frac{1}{2\pi} \int d\Theta_1 d\Theta_2 F(\Theta_1, \Theta_2), \quad (6)$$

where $0 \leq \Theta_k \leq 2\pi$ ($k = 1, 2$) are twist boundary phases for the torus systems. To obtain this integral, we uniformly divide the boundary phase space into $M$ plaquettes ($M$ is chosen up to 100). The Berry curvature defined for each plaquette $l$ is calculated as $F_l = \arg \prod_{i=1}^{4} V_l^{i+1} V_l^i$ ($l = 1, \ldots, M$). The label $i$ ($i = 1, 2, 3, 4$) denotes the four corners of the $l$-th plaquette, where the periodic condition requires $V_l^{i+1} = V_l^i$. The wave function $|\Psi_V^l\rangle$ is the optimized wave function of the mean-field Hamiltonian with twisted boundary conditions, which have the opposite requirements for the spin up and spin down partons, namely $c_j L_x \uparrow = c_j e^{i\theta_k}$ and $c_j L_x \downarrow = c_j e^{-i\theta_k}$ ($k = 1$ and 2, and $L_1 = L_2 = L$ in our calculations). The overlap for the Berry curvature $\langle \Psi_V^{l+1} | \Psi_V^l \rangle = \sum_x P(x) \frac{|\langle x|\Psi_V^{l+1} \rangle|^2}{|\langle x|\Psi_V^l \rangle|^2}$ is calculated by Monte Carlo method according to the weight $P(x) = \frac{|\langle x|\Psi_V^{l+1} \rangle|^2}{\sum_x |\langle x|\Psi_V^l \rangle|^2}$. We obtain the Berry curvatures as shown in Fig. 6. Here, we consider two wave functions. One is the optimized state at $J_2 = 0.1$, $J_X = 0.05$ (flux is obtained as $\theta_1 \approx 0.18$), and the other one for comparison is the state with fluxes $[\pi/2, \pi/2]$. For both states, we do the integration of the Berry curvature from 0 to $2\pi$. We must emphasize that the integration from 0 to $2\pi$ for the operators of two partons (with spin up and spin down) includes two periods of phases for the spin operators, so the final results of the Chern number must be divided by 4 for the spin system. In our calculations, the integrations between 0 and $2\pi$ for both states give the results.
the eight small clusters. Thus, we calculate the overlap matrix on the field band gap to suppress the strong finite-size effects on theromagnet experience of the similar calculations on kagomé antifer-

number of the linearly independent states. Based on the nonzero eigenvalues of this overlap matrix gives the calculate the overlaps between any two of the four states of the fermionic variational wave functions accord-

tion is consistent with number of the linear independence of the mean field Hamiltonian to either periodic or antiperiodic boundary condition and $\pi$ for antiperiodic boundary condition ($i = 1, 2$), i.e., these four projected states are $\{|0, 0\}, |0, \pi\}, |\pi, 0\}, |\pi, \pi\}$. Then we can calculate the overlaps between any two of the four states to obtain the overlap matrix, and the number of the nonzero eigenvalues of this overlap matrix gives the number of the linearly independent states. Based on the experience of the similar calculations on kagomé antiferromagnet, we should choose a state with a big mean-field band gap to suppress the strong finite-size effects on small clusters. Thus, we calculate the overlap matrix on the $8 \times 8$ cluster for the state with flux $\theta_1 = \pi/2$ (this state has a big mean-field band gap 4.1), and obtain the overlap matrix $O$ as

\[
O = \begin{pmatrix}
1 & 0.57 & 0.57 & 0.57 \\
0.57 & 1 & 0.58e^{i1.59} & 0.58e^{i1.59} \\
0.57 & 0.58e^{i1.59} & 1 & 0.58e^{i1.59} \\
0.57 & 0.58e^{i1.59} & 0.58e^{i1.59} & 1
\end{pmatrix}.
\]

In this calculation, we fix the global phases in such a way that all the overlaps with $|0, 0\rangle$ are set to real. The number of the independent ground states can be found by diagonalizing the overlap matrix, i.e., $O = U^\dagger \Lambda U$. We find that only two eigenvalues are non-zero, which indicates that only two eigenvectors are linearly independent. This fact implies that the ground-state degeneracy is two-fold. Our calculations of topological Chern number and ground state degeneracy consistently suggest that this chiral state is the $\nu = 1/2$ Laughlin state.

B. Anisotropic system with $J_1 \neq J'_1$

In the DMRG studies on the $J_1 - J_2$ triangular model, a weak chiral order is found on the finite-size system in the even sector, and by tuning the bond anisotropy $J_1$ and $J'_1$ ($J_1$ and $J'_1$ are along the vertical and the zigzag directions, respectively) the chiral order seems to enhance with $J_1 - J'_1$ for $0.96 \lesssim J_1/J_1 \lesssim 1.04$. The bond anisotropy and chiral order appear to have interesting competition. In this part, we introduce the bond spatial anisotropy in the $J_1 - J_2 - J_3$ model to study this competition. We choose $J_2 = J_3 = 0.1$ and change the anisotropy $J'_1$ from 0.96 to 1.04. Correspondingly, we use the variational wave function with $t_1 \neq t'_1$ (see Fig. 1(b)). Thus, there are three variational parameters (imaginary part of $t_1$, real and imaginary parts of $t'_1$), including two fluxes that need to be optimized. Since the optimizations with two fluxes are very time consuming, we only did variational calculations on the $L = 12$ and 18 clusters.

As shown in Fig. 7(a), we find that once $J'_1 \neq J_1$, we obtain $|t_1| \neq |t'_1|$ after optimization, which indicates that the optimized wave functions break lattice rotational symmetry. Then, we measure the spin chirality $\langle \chi \rangle$ for different $J'_1$. Interestingly, as shown in Fig. 7(b), we find that when $J'_1 < J_1$, the chiral order is enhanced with increasing anisotropy $|J_1 - J'_1|$; on the contrary when $J'_1 > J_1$, chiral order is suppressed with increasing $|J_1 - J'_1|$. 

FIG. 5: (Color online) The chiral order parameter $\langle \chi \rangle$ of the optimized wave functions. For the up and down triangles, we obtain the same value of $\langle \chi \rangle$ within the error bar. The inset is the finite size scaling for the chirality $\langle \chi \rangle$ at $J_\chi = 0.02, 0.05$, and 0.1.
FIG. 6: (Color online) Berry curvature for the states of (a) $J_2 = 0.1, J_\chi = 0.05$ on the $L = 12$ lattice and (b) $[\pi/2, \pi/2]$ on the $L = 8$ lattice. For both calculations, the Brillouin zone is divided into a mesh with 100 plaquettes. The summation between 0 and $2\pi$ gives $C = 1.998$ (a) and 1.999 (b).

V. CONCLUSIONS

We have studied the spin-1/2 antiferromagnetic $J_1 - J_2$ Heisenberg model with additional chiral coupling $J_\chi S_i \cdot (S_j \times S_k)$ on the triangular lattice. By performing the variational Monte Carlo simulations and considering different variational wave functions, we find that while the 120° Néel order vanishes at a finite $J_\chi$, and the gapless U(1) Dirac spin liquid in the intermediate regime would become a chiral spin liquid once $J_\chi$ starts to grow. By calculating the topological Chern number and ground-state degeneracy, we identify this CSL as the $\nu = 1/2$ Laughlin state. We also consider the relation between the chiral order and the spatial anisotropy in the model, and we find that the chiral order can be enhanced (suppressed) when the anisotropic parameter $J'_1 < J_1$ ($J'_1 > J_1$), which is consistent with the DMRG observation. Our results suggest a new way to stabilize a chiral spin liquid near the $J_1 - J_2$ triangular model. Finally we would like to mention that we have not considered all the possible variational states, and it is worth to use unbiased numerical simulations such as DMRG to clarify the phase diagram and the properties of the ground states.
