Vortices are ubiquitous in Nature. They play a fundamental role in various physical systems and one of their fascinating features is a possibility to create a variety of periodic structures. Examples are fluids [1], superconductors of type II where vortices and vortex lattices are created under the action of magnetic field [2]; vortices and their arrays nucleate in rotating superfluid helium [3] and BEC [4]. Submicron size magnetic nanoparticles give another example where the vortices play crucial role. These nanoparticles due to interplay between short-range exchange interaction and long-range dipole interaction have a curling ground state [5]. One way to control the behavior of nanomagnets is to pass a spin-polarized current through the nanodot. As was discovered by Slonczewski [6] and Berger [7], the spin-polarized current acts as an effective spin-torque, which is an important feature for design of electrically controlled devices of spintronics [8].

It was shown theoretically [9,11] and experimentally [11] that the dc spin-polarized current passing perpendicularly to the nanodisk can excite the circular motion of the vortex core. Such a circular motion can be excited [9] under two conditions: the current density $|j|$ exceeds some critical value $j_c$ and $j \sigma p < 0$, where $\sigma = \pm 1$ is direction of spin polarization of the current (along the normal to the nanodisk $\hat{z}$), and $p = \pm 1$ is the vortex polarity (the direction of the vortex core magnetization). When $j \sigma p > 0$, the vortex core remains at the center of the disk.

The aim of this Letter is to show that passing the spin-polarized electrical current with $j \sigma p > 0$ through magnetic nanodisks can lead to creation of periodic vortex-antivortex arrays. This is a phenomenon with a threshold: it occurs when the current density exceeds some critical value which depends on material parameters of the nanomagnet and its sizes. In the Letter we report about numerical investigation of influence of the spin-polarized current on vortex state nanodisk for wide range of current densities. Our micromagnetic simulations [12] are based on the Landau-Lifshitz-Slonczewski equation [6,7,13]:

$$\dot{m} = m \times \delta \varepsilon / \delta m + \alpha [m \times \dot{m}] - \sigma j \varepsilon m \times [m \times \hat{z}].$$

(1)

Here $m = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$ is a normalized magnetization, the overdot indicates derivative with respect to the rescaled time in units of $(4 \pi \gamma M_s)^{-1}$, $\gamma$ is gyromagnetic ratio, $M_s$ is the saturation magnetization, and $\varepsilon = E/(4 \pi M_s^2)$ is normalized magnetic energy. The normalized electrical current density $j = J/J_0$, where $J_0 = M_s^2 |e| \hbar / h$ with $e$ being electron charge, $h$ being the sample thickness and $\hbar$ being Planck constant. Here and below it is assumed that the current flow and its spin-polarization are directed along $\hat{z}$-axis. The spin-transfer torque efficiency function $\varepsilon$ has the form $\varepsilon = \eta \Lambda^2 / [(\Lambda^2 + 1) + (\Lambda^2 - 1) \sigma (m \cdot \hat{z})]$, where $\eta$ is the degree of spin polarization and parameter $\Lambda$ describes the mismatch between spacer and ferromagnet resistance [13,14].

Studying response of the vortex state to the spin-transfer torque one can distinguish two critical current densities: $j_1$ and $j_2$. When $j < j_1$ the stationary state of the system is a deformed vortex state (see below). When $j > j_2$ the system goes in a saturated state when all spins are aligned along $\hat{z}$-axis. When $j_1 < j < j_2$ a rich variety of dynamic states is observed: the system demonstrates either chaotic dynamics of vortex-antivortex 2D gas or regular and stable vortex-antivortex lattices.

In the no-driving case the ground state of the nanodot is a vortex state with $\cos \theta_c = p f(r)$ where an exponentially localized function $f(r)$ describes the vortex core profile, and $\phi_c = \chi \pm \pi/2$ ($r, \chi$ are polar coordinates originated in the disk center). First of all we studied how the ground vortex state $\theta_c, \phi_c$ is modified under an influence of the spin-polarized current. Starting from the current $j = 0$ we increased $j$ step by step with full relaxation on each step and with size of the step $\Delta j \ll j_1$. A typical deformed vortex state is shown in the lower inset of the Fig. [1]. Changes of the out-of-plane component of the vortex distribution are negligibly small ($\theta \approx \theta_c$),

**Current induced vortex superlattices in nanomagnets**

Influence of the spin-transfer torque on the vortex state magnetic nanodisk is studied numerically via Slonczewski-Berger mechanism. The existence of a critical current is determined for the case of same-directed electrical current, its spin polarization and polarity of the vortex. The critical current separates two regimes: (i) deformed but static vortex state and (ii) essentially dynamic state under which the spatio-temporal periodic structures can appear. The structure is a stable vortex-antivortex lattice. Symmetry of the lattice depends on the applied current value and for high currents (close to saturation) only square lattices are observed. General relations for sizes of the stable lattice is obtained analytically.

while the in-plane structure is deformed appreciably and can be described as \( \phi = \phi_0 + \psi(r) \). The deformation \( \psi \) is a non-monotonic function of \( r \). Its amplitude is an increasing function of the current strength \( j \). The presence of the deformation function \( \psi(r) \) means an appearance of volume magnetostatic charges and increase of corresponding magnetostatic energy. As a result at \( j = j_1 \), the vortex at the center of disk ceases to be a stable stationary state. The vortex escapes from the disk center moving in a spiral trajectory. The critical current \( j_1 \) is an increasing function of the disk thickness (see Fig. 1). This fact emphasizes the important role of the volume magnetostatic charges in the phenomenon. The mentioned spiral vortex motion is accompanied by intensive generation of the magnons and results in appearance of a gas of vortex-antivortex pairs. As a rule the motion vortices in this state is quite irregular. However, for some values of the current in the range \( (j_1, j_2) \) instead of chaotic gas-like dynamics stable spatially regular vortex-antivortex structures appear (as an example, see upper inset of the Fig. 1). The following part of the Letter is devoted to studying this phenomenon.

To study the observed superstructures in detail we used two methods: (i) the spin current of the certain density is sharply applied to the vortex state nanodisk; (ii) the nanodisk is previously saturated to the uniform state by a strong external magnetic field which is applied perpendicularly to the disk plane, then the current of necessary density is switched on and the external field is adiabatically diminished down to zero: \( B = e^{-t/\tau}[B_0 \hat{z} + b(r, t)] \), where \( B_0 \) is saturation field, time parameter \( \tau \) is much greater than the typical time of spin waves dissipation and additional field \( b \) with \( |b| \ll B_0 \) was added to avoid instable equilibrium states.

Possible vortex-antivortex structures which appear for \( j_1 < j < j_2 \) are classified and shown in the Fig. 2. The obtained current diagram has the following properties: (i) the regular structures appear in the vicinity of the critical currents \( j_1 \) and \( j_2 \); (ii) the regions where the regular structures exist, become wider with disk thickness increasing and these regions vanish for thin disks; (iii) regular structures have a well pronounced symmetry: a system with rotary-reflection \( S_2 \) symmetry and systems with rotational \( C_n \) \( (n = 3, 4, 6) \) symmetry were observed. They rotate bodily around the disk center with frequency much lower then the corresponding gyrofrequency of the free vortex. The magnitude of the rotation frequency and its sign depend on the current; (iv) the structures become more compact with the current increasing; (v) for the currents close to \( j_2 \) a crystal-like structure with a square lattice appears; (vi) as the current decreases line defects appear in such vortex-antivortex crystals, see inset “f” of the Fig. 2 (the defects are surrounded by dashed circles). As a result the crystal loses the long-range symmetry but a short-range order is preserved: each vortex has four nearest neighbors-antivortices and vice versa. The defects permanently move within the structure and the whole dynamics is similar to the dynamics in fluids; (vii) further decrease of the current destroys the short-range order in the system and a vortex-antivortex gas phase appears.

It is important to note that the crystal-like structures appear in current driven nanodots even in the no-damping case \( (\alpha = 0) \) and the interval of their existence only weakly depends on the damping coefficient \( \alpha \) and does not depend on the method of structure creation. In contrast to this, the thresholds and the intervals of existence of regular structures with a few vortex-antivortex pairs depend both on the damping coefficient and on the method of generation. These regular structures exist also in the no-damping case.

The total vorticity \( q = \sum_{k=1}^{N} q_k \), where \( N \) is the total number of the particles: vortices (the winding number \( q_k = +1 \)), antivortices \( (q_k = -1) \), is the same for all regular structures and it is equal to +1 (as for the single vortex). The structures with a few vortex-antivortex pairs also have \( q = 1 \) if one takes into account edge solitons. The edge soliton is a half of an antivortex which moves on the disk edge and it has the winding number \( q_k = -1/2 \). Each of above-mentioned regular vortex-antivortex structures represents a stationary state of the system. It means that the energy \( E \) and the total momentum \( J = \int (\cos \theta - 1)(1 - \partial_\phi \phi) d\mathbf{r} \) must be time independent. Considering as the most intriguing the no-

![FIG. 1. (Color online.) Dependence of critical current \( J_1 \) on the nanodisk thickness for different disk diameters. Insets show magnetization structures in nanodisk with \( D = 250 \) nm and \( h = 15 \) nm for different current densities: \( J = 5.75 \cdot 10^{12} \) A/m² ≤ \( J_1 \) (bottom right inset), \( J = 6 \cdot 10^{12} \) A/m² ≥ \( J_1 \) (upper left inset).](image-url)
where the particles cores is much smaller than the disk area $S$ into the expressions (2) and assuming that total area of one can obtain polar coordinates of the $k$-th particle. Substituting (3) into the expressions (2) and assuming that total area of the particles cores is much smaller than the disk area $S$ one can obtain

$$
\hat{\omega} = -\sigma \int \varepsilon \sin^2 \theta \, \hat{\omega} \, d\mathbf{r},
$$

$$
\hat{\phi} = \sigma \int \varepsilon \sin^2 \theta (1 - \partial_\chi \phi) \, d\mathbf{r} \tag{2}
$$

To describe the multiple vortex-antivortex structure the following ansatz can be used:

$$
\cos \theta = \sum_{k=1}^{N} f(|z - Z_k|), \quad \phi = \sum_{k=1}^{N} q_k \arg(z - Z_k),
$$

(3)

where $z = r e^{i\chi}$ and $Z_k = R_k e^{i\phi_k}$ with $(R_k, \Phi_k)$ being polar coordinates of the $k$-th particle. Substituting (3) into the expressions (2) and assuming that total area of the particles cores is much smaller than the disk area $S$ one can obtain

$$
\hat{\omega} \approx -\sigma \xi \hat{\omega}, \quad \hat{\phi} \approx \pi h \sum_{k} q_k R_k^2 + S h (1 - \sum_{k} q_k)
$$

$$
\hat{\epsilon} \approx -\pi h \sigma j \xi \sum_{k} q_k R_k^2 \Phi_k, \tag{4}
$$

where $\xi = \eta \Lambda^2/(\Lambda^2 + 1)$. Thus the stationarity conditions \( \hat{\epsilon} = 0 \) and \( \hat{\phi} = 0 \) can be satisfied if

$$
q = \sum_{k=1}^{N} q_k = 1, \quad \sum_{k} q_k R_k^2 = 0, \quad \Phi_k = \Omega = \text{const.} \tag{5}
$$

Moreover, in process of the structure formation \( \hat{\omega} = \hat{\omega}_0 \exp(-t/t_0) \), where $t_0 = (\sigma \xi j)^{-1}$ is typical time of the formation, and systems with total vorticity $q = 1$ have linear dependence between energy and momentum: $\hat{\omega} = \Omega \hat{\phi}$. For all regular structures obtained in the simulations $\sum_k q_k = 1$ (taking into account edge solitons), $\Phi_k = \text{const}$ and $|\sum_k q_k (R_k/L)^2| \lesssim 10^{-2}$ with $L$ being the disk radius.

To validate our analytical considerations we carried out a direct stability check. To this end we first applied the field pulse in disk plane (red arrow), which was spatially localized nearby the central vortex in a circular range of 50 nm in diameter, keeping the rest of the magnetization distribution artificially fixed during the field pulse time, see Fig. 3(a). Such a field pulse shifts a vortex perpendicular to the field direction. After the pulse was switched off the spin–current induced magnetization dynamics was simulated as usual. We found that the vortex was turned back to its origin in a short time (about 60 ps) and a whole structure continued its rotation, see Fig. 3(b).
The similar picture takes place for the antivortex stability, cf. Figs. 3(1) and 3(3). It allows to conclude that the superstructure is locally stable: only the strong field pulse can destroy the structure.

In conclusion, we observed for the first time and studied numerically the spatially periodic vortex–antivortex structures which appear in nanomagnets under influence of spin-transfer torque. The structure formation is only weekly influenced by Gilbert damping [17], it results from effective dissipation induced by the spin current. We demonstrated analytically and proved numerically fulfillment of conditions [5] for the periodic structures.
