Abstract

Frequency response analysis (FRA) of systems is a well-researched area. For years, FRA has been performed using input signals, which are a series of sinusoids or a sum of sinusoids. This results in large experimentation time, particularly when the system has to be probed at lower frequencies. In this work, we describe a previously unknown time-frequency duality for linear systems when probed through chirp signals. We show that the entire frequency response can be extracted with a single chirp signal by extending the notion of instantaneous frequency to both the input and output signals. It is surprising that this powerful result had not been uncovered given that FRA has been used in multiple disciplines for more than hundred years. This result has the possibility of completely revolutionizing methods used for frequency response analysis. Simulation studies that support the main result are described. While this result is of relevance in multiple areas, we demonstrate the potential impact of this result in electrochemical impedance spectroscopy.

Keywords: Frequency Response Analysis, Nyquist plot, Impedance, Chirp signals, EIS

1 Introduction

A system can be characterized by how it responds to sinusoidal input perturbations, also known as the frequency response analysis (FRA). The frequency response at a particular frequency can be specified as a ratio of the output to input, represented as a complex number. Since frequency response is computed from time series data, an equivalence between time and frequency needs to be established. This is directly realized through the well-known Fourier Transform, which allows any time domain signal to be decomposed into its constituent frequency components. A standard approach for FRA of a system is to perturb the system with an input, which is usually a series of sine signals or a sum of sine (multi-sine) signal [29, 25] and identify the frequency response from the output data. A key observation here is that to generate one point in the frequency domain, all the time domain data needs to be processed. This is referred to as the localization problem. A direct consequence of this problem is that large experimentation times are needed for generating the complete frequency response of the system and there are also other issues related to deconvolution of the various frequency components from the time domain signal.

There have been several attempts that have been made over the years to address the localization problem [17, 11]. The ideal case would be for a single time point to be localized to a single frequency, which is theoretically not possible. Short term Fourier transforms (STFT) [1] and Wavelet transforms (WT) [11, 17] are some of the time frequency localization approaches that have been attempted. Hilbert-Huang-Transforms (HHT) is another approach that is focused on addressing this problem [16]. In HHT, from a time domain signal, the so-called intrinsic mode functions (IMF) are extracted, which are as close to monochromatic as possible. Hilbert transforms of the IMF then provide some measure of time frequency localization. However, none of these techniques (STFT, WT, HHT) specifically focus on generating an exact time frequency equivalence.
Another approach towards time frequency localization is the use of chirp signals [13, 8, 5, 15]. The interest in chirp signals is due to the fact that it is possible to define a "so called" instantaneous frequency, which is a differential of the phase function of a sinusoid. As a result, a notional frequency can be assigned to every time point in the input signal. Although this notion of one-to-one mapping between time and frequency could be carried over to the output response for linear systems, work in extant literature is focused exclusively on using chirp signals for data generation to be processed by other techniques such as STFT [10, 30, 26] or WT [3] and less on exploring the implications of the interesting time-frequency localization that chirp signals afford. This might also be because instantaneous frequency as a concept itself is not well accepted and/or understood [4, 21]. There has been interest in interpreting instantaneous frequency and exploring connections between standard techniques such as FFT and chirp, but still only in terms of information content in the signal and not from viewing two time series (input and output) as having the same frequency variation across time [21, 20]. Our prior work [6, 28] comes closest to exploring the time-frequency equivalence proposed here; however, we just proposed an algorithm for FRA of electrochemical systems. We claimed that our algorithm was an approximate method for FRA; the impact of time-frequency equivalence was neither clearly understood nor carefully explored at that time. Summarizing, a fundamental question that is of interest is the following: is there a direct one-to-one equivalence between the time domain behavior and the frequency domain behavior that can be established by assigning a single frequency to every time point in a time series data? In this paper, we describe an unexplored equivalence in the case of linear systems when the two time series data (input and output) are hypothesized to possess the same one-to-one time-frequency mapping. This equivalence allows the direct computation of the frequency characteristics from time domain data without ever performing any transformations. It also substantiates the usefulness of the previously hypothesized instantaneous frequency. Finally, the result is an asymptotic result, much in the same format as the well-known time frequency equivalence result for a single frequency input perturbation. In this paper, we discuss the main result and various computational studies that validate the main result. For the sake of brevity, we present the significance of the main result and its implications in this paper. A detailed proof in support of the main result and other mathematical details are available in [27].

1.1 Preliminaries

A chirp signal is a signal with time-varying frequency. The generic form of a chirp signal is \( u(t) = A \sin(\phi(t)) \) where \( \phi(t) \) is the instantaneous phase. The instantaneous angular frequency of the signal at any instant \( t \) is defined as the differential of the instantaneous phase of the sinusoid at time \( t \) (\( \omega(t) = 2\pi f(t) = \frac{d\phi(t)}{dt} \)). One can see from the definition of chirp signal that the phase function \( \phi(t) \) is not assumed to take any particular form. Linear chirp defined below has been a popular choice.

**Linear Chirp:** \( u(t) = \sin(\phi_0 + 2\pi(f_0 t + 0.5h_1 t^2)) \) (1)

where \( f(t) = f_0 + h_1 t \) is the linear instantaneous frequency and \( \phi_0 \) is the initial phase. One could generalize this linear chirp to \( n^{th} \) order polynomial chirp, whose phase function \( \phi(t) = P_{n+1}(t) \), is an \((n + 1)^{th}\) order polynomial.

2 Results

We start with a very well-known result in the area of system identification.

**Lemma 1.** When a stable, strictly causal linear system \( G(s) \) is perturbed with an input sine signal \( u_i(t) = A_i \sin(\omega t; \ \omega = 2\pi f) \), as time \( t \) tends to infinity, output of the system \( x(t) \) is also a sine signal with the same frequency as the input but with an amplitude ratio and phase lag.

\[
x(t) = A_{in} AR(\omega) \sin(\omega t + \phi_L(\omega)) + E(t)
\]

(2)

where \( AR(\omega) \) and \( \phi_L(\omega) \) are the amplitude ratio and phase lag at angular frequency \( \omega \). Also, \( E(t) = 0 \) and thus,

\[
x(t) \xrightarrow{t \to \infty} A_{in} AR(\omega) \sin(\omega t + \phi_L(\omega))
\]

(3)
This result has been used for decades now and is the foundation on which FRA has progressed. Using this result, the frequency response of the system as a complex number can be identified at each frequency by perturbing the system at every frequency of interest. However, a major disadvantage of this result is that, to derive the complete frequency response, the system has to be perturbed at several frequencies individually. This is sometimes simplified using a sum of sines input and deconvolution of the output using fast Fourier transform (FFT) \[7\]. Notice that this is an asymptotic result and hence one would have to wait for a certain amount of time for the transients to dissipate before the frequency response is identified. We now present the main result derived in this paper and contrast that with Lemma 1.

**Main Result.** When a stable, strictly causal linear system $G(s)$ is perturbed with a chirp signal $u(t) = A_{in} \sin \phi(t)$, as time $t$ tends to infinity, the output of the system is also a chirp signal such that the instantaneous amplitude ratio ($AR_{ch}$) and phase lag ($\phi_{ch}^L$) of the chirp signal are same as the true amplitude ratio and phase lag of the system corresponding to the instantaneous frequency.

$$x(t) = A_{in}AR_{ch}(t) \sin \left( \phi(t) + \phi_{ch}^L(t) \right) + E_{ch}(t) \quad (4)$$

$$AR_{ch}(t) \bigg|_{t=\psi^{-1}(\omega)} = AR(\omega) \quad (5)$$

$$\phi_{ch}^L(t) \bigg|_{t=\psi^{-1}(\omega)} = \phi_{ch}^L(\omega) \quad (6)$$

$$E_{ch}(t) \bigg|_{t\rightarrow\infty} = 0 \quad (7)$$

Angular frequency, $\omega = \psi(t) = \frac{d\phi(t)}{dt}$, is a known quantity from the one-to-one mapping between time and frequency of the input chirp signal.
In summary, the asymptotic output response of the system to an input chirp signal can be written as:

\[
x(t) = A_{in}AR(\psi(t)) \sin (\phi(t) + \phi_L(\psi(t)))
\]  

(8)

We will now validate the claims proposed in this paper through simulation studies. While we have validated the claims on a large number of linear systems with different characteristics, we report results for six different systems of various characteristics in terms of zeros, poles (repeated and not repeated), and orders as shown in Table 1. To validate the claim, we compare the true chirp response \( x(t) \) of these systems to unit amplitude chirp input and the asymptotic output behavior \( x(t) \) as predicted by (8) in Figure 2. Responses corresponding to both linear and fourth order chirp inputs are provided. Linear chirp input signal that is used sweeps frequencies from 1 Hz to 400 Hz in 10 seconds, while the fourth order chirp input used for the study sweeps frequencies from 1 Hz to 1000 Hz in 10 seconds. An immediate observation from Figure 2 is that in both cases, the envelope of \( x(t) \) converges to the true \( AR \) and \( x(t) \) converges to \( x(t) \), very rapidly, within a couple of cycles. To illustrate this, the error \( (x(t) - x(t)) \) is plotted in Figure 3 for both linear and fourth order chirp responses. It can be seen that the error converges to zero within a short time for both linear and fourth order chirp signals.

The choice of the phase function does have an effect on the speed at which the errors might vanish. However, remarkably, the one-to-one time frequency relationship is retained for different phase functions. The theoretical analysis and the proofs presented in [27] describe the mathematics that underlie these observations. The Nyquist plots generated for these examples are provided in Figure 4. It can be seen that the Nyquist profiles match the theoretically computed ones extremely accurately. The chirp signal-based FRA using more than 50000 samples takes approximately 0.25 seconds in an eighth generation i7 processor and, thus, is not computationally expensive. It can also be seen that response for a larger frequency range is obtained using a fourth order chirp compared to a linear chirp signal in the same duration. However, for the same experimentation time, within the range of frequency covered by the linear chirp, the resolution will be better for the linear chirp than the fourth order chirp. These simulation results demonstrate the significant application potential for chirp-based FRA.

### 3 Discussion

The first thing to notice about the main result is that this is also an asymptotic result (much like Lemma 1), where a certain time profile for the output remains after the transients vanish. However, the final time profile that is shown to be retained is the key difference between Lemma 1 and the main result. In Lemma 1, the time profile is a sinusoid of a fixed frequency and a constant amplitude and phase lag. However, in the main result, the time profile is a chirp signal with time varying frequency, amplitude, and phase. Let us remember that the differential of the phase of the sinusoid (time function) was defined as the instantaneous frequency at a time point. The amplitude and phase of the output are time functions. Since we have an one-to-one equivalence between time and frequency, we can replace the time variable in the expressions for magnitude and phase with the corresponding frequency function. This would result in magnitude and phase becoming functions of frequency.
Figure 2: Response of various systems to linear and fourth order chirp inputs. Zoomed responses are given in the inset.
The main result now provides a remarkable equivalence in that the frequency functions so derived from
the output time profiles are exactly equal to the corresponding frequency response functions that would have
resulted from applying Lemma 1 for multiple frequencies, once transients vanish. In other words, we now
have one frequency defined for every time point and incredibly, all the frequency information is located at
that time point. Of course, it is important to reiterate that this is an asymptotic property (like Lemma
1); however, we have demonstrated that the error vanishes very rapidly, making this result of tremendous
practical value much like the result described in Lemma 1, which has been used for decades now.

The most important implication of this result is that the time required for identifying the FR of the
system can be brought down dramatically. This is illustrated in Figure 1, where one sees that a single point
in the Nyquist plot corresponds to a signal in FR analysis. In the series of sines approach, these signals are
combined serially and this increases the testing times significantly. In the sum of the sines approach, these
signals are overlaid; however, to generate a point in the Nyquist plot, the output has to be deconvolved as
responses to each of these sine signals and issues related to spectral leakage and other difficulties need to
be addressed [29, 7]. Further, the length of the signal is determined by the lowest frequency that one is
interested in exploring. The main result in this paper provides us a totally new approach to solving this
problem, wherein a single time point in the input signal corresponds to one point in the Nyquist plot (Figure
1). This allows the exploration of multiple frequencies in dramatically reduced experimentation time.

We have presented the key statement of the main result here. All the theoretical underpinnings and a
proof for this result for general linear systems with repeated and non-repeated poles along with conditions on
admissible phase functions are all comprehensively described in [27]. One can see that many functional forms
can satisfy the conditions for admissible phase function; however, from a practical demonstration viewpoint
we will focus on polynomial chirp signals in this paper.

3.1 Relevance to Electrochemical Impedance Spectroscopy

While FRA is used in almost all engineering fields, in this section, we will show the relevance of the theo-
retical developments reported in this paper for electrochemical impedance spectroscopy (EIS). The notion
of impedance has been around since the late 1800s with impedance being defined for the first time by Oliver
Heaviside and this quantity represented as a complex number by Arthur Kennelly in the 1890s [19]. EIS
Figure 4: Nyquist plots generated using linear and fourth order chirp analysis in comparison with the theoretical frequency response for various systems. Nyquist plots generated using linear and fourth order chirp responses are for the input frequency range [1Hz 400Hz] and [1Hz 1000Hz] respectively.
Table 2: Comparison of standard EIS and chirp signal-based EIS

(a) General comparison

|                      | Standard EIS | Chirp signal-based EIS |
|----------------------|--------------|------------------------|
| **Input signal**     | Sinusoidal   | Chirp (Linear/Polynomial) |
| **Frequency of input signal** | Constant | Varying |
| **No. of signals needed** | Depends on the no. of frequencies needed | 1 |
| **Time required**    | Depends on the no. of frequencies needed | Depends on the frequency range |
| **No. of data points in the plot** | Same as no. of signals | Same as total samples in the signal |

(b) Example with fourth order chirp input that sweeps through the frequency range 0.001Hz to 10000Hz at a sampling rate, \( r = 10,000 \) samples/sec

|                      | Standard EIS | Chirp signal-based EIS |
|----------------------|--------------|------------------------|
| **Input signal**     | \( A_{in} \sin(2\pi ft) \) | \( A_{in} \sin(\phi(t)); \quad \phi = P_5(t); \quad f = \frac{df}{dt} \) |
| **Output signal (steady-state)** | \( A_{in} A_F \sin(2\pi f t + \phi_L) \) | \( A_{in} A_F R^{ch}(t) \sin(\phi(t) + \phi^{ch}_L(t)) \) |
| **No. of cycles per signal needed** | 60 (Assume) | 1 |
| **Signal duration, \( T \)** | 2.66 hours | 100 sec |
| **No. of data points in the plot** | 60 | \( 10^6 \) (\( = r \times T \)) |

is essentially FRA of systems with the input and output being current and voltage respectively. EIS has been used for diagnostics in various electrochemical systems finding applications in disparate problem domains such as corrosion studies [22, 23], sensors [18], biological systems [9, 14], concrete characterization [2, 24], body fat estimation [12], and many others. Impedance as a diagnostic measure cross-cuts almost all engineering and science disciplines. In view of this universality and continued relevance, there have been thousands of papers that have been devoted to this field. For example, Google scholar has 44603 articles with the keyword ‘Electrochemical Impedance Spectroscopy’ just for a two year period from 2018. Similarly, ScienDirect and Scopus has 38,727 and 59,856 articles with the same keyword for the same duration.

We are now in a position to describe the impact of the main result reported in this paper on EIS. If the chirp analysis procedure is followed instead of a series of sinusoidal signals for EIS, then the significance will become apparent. Table 2b outlines the advantages of chirp signals for EIS assuming a frequency range 1 mHz to 10 kHz with a sampling rate of 10000 samples/sec and a fourth order chirp signal. It can be seen that chirp analysis will require only 100 seconds to extract impedance information for 10\(^6\) different frequencies, while standard EIS analysis would require 2.66 hours to extract the impedance information for 60 different frequencies. Table 2a summarizes the main features of the chirp signal-based EIS.

4 Methods

Based on the main result, it is possible to extract the entire frequency response using a single chirp perturbation experiment unlike standard FRA, where \( n \) sinusoidal perturbation experiments would be required to acquire frequency information for \( n \) different frequencies with a series of sines. As discussed already, if a multi-sine signal were to be used, the time required would still be dictated by the smallest frequency of interest. As a corollary to the main result, a procedure for generating the Nyquist plot (polar representation of the frequency response obtained by expressing amplitude ratio and phase lag as a complex number) can be developed as shown below:

1. Perturb the system with a chirp input signal of amplitude \( A_{in} \) and collect the system’s response
2. Obtain the outer envelope of output signal to obtain \( A^{ch} \)
3. Calculate amplitude ratio, \( AR^{ch} = \frac{A^{ch}}{A_{in}} \)
4. Calculate output phase \( (\phi + \phi_{ch}^{L}) \) using (8)
5. Unwrap the output phase to a smooth monotonically increasing function

6. Calculate phase lag, $\phi_{ch}^L$, by subtracting the input phase ($\phi$) from the output phase obtained in Step 4

7. Generate Nyquist plot using the complex number, $z(\omega) = AR^{ch}(\omega)e^{i\phi_{ch}^L(\omega)}$

5 Conclusions

In summary, a novel result of this work is that it is possible to extract the entire frequency response from short-term time signals. This result is supported through theoretical analysis and extensive simulation results. The analysis provides an initial assessment of the rate of convergence of the error term. We have verified this result for a large number of linear systems with different characteristics (in terms of zeros and poles). Theoretical proof of its validity for any general linear system is provided elsewhere ([27]). The relationship between error convergence rates and the choice of phase functions should be more carefully explored. Further, the implications of this approach vis a vis the notion of harmonics in frequency response analysis of nonlinear systems need to be explored. Additionally, we have considered monotonically increasing frequency functions, similar analysis needs to be performed for non-monotonic functions. This can open up new ideas for simple nonlinearity detection techniques purely from the response to an appropriately designed chirp signal. Further, the implications of this result from a general system identification viewpoint needs to be assessed. While it has been shown, conceptually, that the whole frequency response can be extracted with large bandwidth short-time signals, there are several practical implementation issues that need to be addressed. These are concerns related to the effect of noise, sampling rates, and non-stationarities. Some of our initial work has started to address these practical implementation issues [6, 28]. More sophisticated iterative algorithms for processing the chirp response data can be developed that can minimize, even more, the effect of error terms in the initial segment of data and the corresponding frequency response identification.

Other than the literature associated with system identification, the approach described in this paper has a role to play in all fields where impedance is used. Impedance being a fundamental characteristic of the system, has been used in various applications [24, 23, 14]; however, many of these studies were limited to higher frequencies (> 1Hz) as the time required for impedance generation at low frequencies is usually unacceptably large. Since the impedance information from chirp analysis is obtained in a much shorter time (even at low frequencies), chirp analysis has the potential to become the technique of choice for EIS in all of these applications.
