Detection, Measurement and Gravitational Radiation

Lee S. Finn

Department of Physics and Astronomy, Northwestern University, Evanston Illinois 60208

(Received )

The optimum design, construction, and use of the LIGO, VIRGO, or LAGOS gravitational radiation detectors depends upon accurate calculations of their sensitivity to different sources of radiation. Here I examine how to determine the sensitivity of these instruments to sources of gravitational radiation by considering the process by which data are analyzed in a noisy detector. The problem of detection (is a signal present in the output of the detector?) is separated from that of measurement (what are the parameters that characterize the signal in the detector output?). By constructing the probability that the detector output is consistent with the presence of a signal, I show how to quantify the uncertainty that the output contains a signal and is not simply noise. Proceeding further, I construct the probability distribution that the parameterization \( \mu \) that characterizes the signal has a certain value. From the distribution and its mode I determine volumes \( V(P) \) in parameter space such that \( \mu \in V(P) \) with probability \( P \) [owing to the random nature of the detector noise, the volumes \( V(P) \) are always different, even for identical signals in the detector output], thus quantifying the uncertainty in the estimation of the signal parameterization.

These techniques are suitable for analyzing the output of a noisy detector. If we are designing a detector, or determining the suitability of an existing detector for observing a new source, then we don’t have detector output to analyze but are interested in the “most likely” response of the detector to a signal. I exploit the
techniques just described to determine the “most likely” volumes $V(P)$ for detector output that would result in a parameter probability distribution with given mode.

Finally, as an example, I apply these techniques to determine the anticipated sensitivity of the LIGO and LAGOS detectors to the gravitational radiation from a perturbed Kerr black hole.

I. INTRODUCTION

Under the present schedule, both the United States Laser Interferometer Gravitational Wave Observatory (LIGO [1,2]) and the French/Italian VIRGO [3] will begin operation in the late 1990s. Long before that time, theorists must lay a foundation for the study of gravitational radiation sources. Part of this foundation involves the construction of detailed, parameterized models of the waveforms from expected sources; another part involves the calculation of the anticipated sensitivity of the detector to each of these sources. Calculation of these kinds are not only needed for LIGO and VIRGO: design and technology studies for a Laser Gravitational-wave Observatory in Space (LAGOS) are currently being pursued [4] and calculations of the sensitivity of LAGOS to appropriate sources are needed to guide these studies.

In this paper I address the problem of calculating the anticipated sensitivity of a detector, like LIGO, VIRGO, or LAGOS, to an arbitrary source of gravitational radiation. The problem breaks up into two parts which I term detection and measurement. To “detect” is to decide whether the observed detector output contains a signal from a particular source or is just an example of noise; to “measure” is to assume the presence of a signal in the detector output and to characterize the signal in terms of the parameter(s) that describe the source (and its orientation with respect to the detector).

Echeverria [5] recently examined some of these issues in the particular context of determining the precision with which one could characterize the mass and angular momentum of a perturbed Kerr black hole from observations in a gravitational radiation detector. The foundation of his analysis was the construction of a quantity similar to the signal-to-noise ratio (SNR), and he asserted that the parameters that characterize a signal observed in the output of the detector are those that maximized this quantity. This analysis is limited in two respects (Echeverria & Finn [6]):

1. The validity of the formalism is restricted to the limit of high SNR; and
2. The formalism cannot determine the amplitude of the signal.

In addition, the conceptual basis of this calculation is not compelling: the determination of the parameters characterizing a signal in a noisy detector does not proceed by maximizing the SNR-like quantity defined by Echeverria [5].

In contrast, the techniques developed here are all based upon the construction of probabilities and probability densities. For the problem of detection, I construct the probability that the observed detector output is consistent with the presence (or absence) of a signal. In the case of the measurement problem, where the detector output is assumed to include a signal, the quantity constructed is the probability density that describes the likelihood of a given signal parameterization.

In §II I examine the twin processes of detection and measurement from the point of view of probability theory. The parameters characterizing a signal identified in the output of a noisy detector are defined to be those most likely to have resulted in the observed detector output. Some of the results described in this section are known elsewhere in the context of data analysis: they are included here for completeness and so that they may be compared with the techniques employed in Echeverria [5]. In §II I show how these same techniques can be exploited to evaluate the anticipated sensitivity of an instrument to a signal: i.e., how precisely can the parameterization of a signal observed in the detector be determined. I find both exact and, in the interesting limit of a strong signal, approximate techniques for evaluating the expected precision with which an observed signal can be described. As an example, in §IV I apply the approximate techniques developed in §II to the determination of the parameterization of the gravitational radiation from a perturbed black hole, especially the black hole mass $M$ and dimensionless angular momentum parameter $a$. In §V I briefly compare the methods and results of Echeverria [6] with my own. My conclusions are presented in §VI.
II. DETECTION, MEASUREMENT AND PROBABILITY

In this section I consider two related problems that arise in the analysis of the output of a noisy detector: detection and measurement. The problem of detection is to determine whether or not a signal of known form (i.e., deterministic, though parameterized by one or several unknown parameters) is present in the detector output. The problem of measurement is to determine the values of some or all of the unknown parameters that characterize the observed signal.

Note that the distinction between detection and measurement separates the determination of the presence or absence of the signal from the determination of the parameters that characterize it: detection does not address the value of the unknown parameters, and measurement presumes the signal’s presence.

Detector noise can always conspire to appear as an example of the sought-for signal; alternatively, noise can mask the presence of a signal. In either case, noise interferes with our ability to determine the presence of the signal or the parameters that characterize it. Consequently, any claim of detection must be associated with a probability signifying the degree of certainty that the detected signal is not, in fact, an instance of noise. Similarly, when an observed signal is characterized it is appropriate to specify both a range of parameters and a probability that the signal parameters are in the given range.

For example, I can examine the data stream from a gravitational radiation detector to determine (with some probability) whether the radiation from the $l = |m| = 2$ mode of a perturbed, rotating black hole is present, irrespective of the black hole mass, angular momentum, or orientation with respect to the detector. If I conclude that a signal is present in the data stream, then I can attempt to determine bounds on some or all of these parameters, such that I expect the actual parameters characterizing the signal to fall within those bounds with a given probability.

In the next several subsections I examine detection and measurement in more detail. I assume that the statistical properties of the detector noise are known, and also that the form
of the sought-for signal is known up to one or several parameters. My discussion focuses on determining the probability that a signal of known form is present in the output of a noisy detector, and on determining the probability that the unknown parameters have particular values.

While the discussion in § IV is framed in the context of the measurement of gravitational radiation from astrophysical sources, the questions addressed in this (and the following) section are purely statistical ones and contain nothing that is specific to gravitational radiation, general relativity, or any particular physical system or theory. For more details, the reader may consult Wainstein & Zubakov [7].

A. Detection

Consider a data stream $g(t)$ which represents the output of a detector. The data stream has a noise component $n(t)$ and in addition may have a signal component $m(t)$. The signal component is parameterized by several unknown parameters (denoted collectively as $\mu$, and individually as $\mu_i$); hence

$$g(t) = \begin{cases} n(t) & \text{if signal not present,} \\ n(t) + m(t; \mu) & \text{if signal } m(t; \mu) \text{ present.} \end{cases}$$  

(2.1)

Assume that $\mu$ is continuous, not discrete. I will describe how to determine the probability that $m(t; \mu)$, for undetermined $\mu$, is present in $g(t)$, i.e.,

$$P(m|g) \equiv \begin{pmatrix} \text{The conditional probability that a} \\ \text{signal of the form } m(t; \mu), \text{ for} \\ \text{unknown } \mu, \text{ is present given the} \\ \text{observed data stream } g(t). \end{pmatrix}.$$  

(2.2)

Begin by using Baye’s law of conditional probabilities to re-express $P(m|g)$ as

$$P(m|g) = \frac{P(g|m)P(m)}{P(g)},$$  

(2.3)

where
\[ P(g|m) \equiv \begin{pmatrix} \text{The probability of measuring } g \\ \text{assuming the signal } m \text{ is present.} \end{pmatrix}, \quad (2.4a) \]

\[ P(m) \equiv \begin{pmatrix} \text{The a priori probability} \\ \text{that the signal } m \text{ is present.} \end{pmatrix}, \quad (2.4b) \]

\[ P(g) \equiv \begin{pmatrix} \text{The probability that the} \\ \text{data stream } g(t) \text{ is observed.} \end{pmatrix}. \quad (2.4c) \]

Also re-express \( P(g) \) in terms of the two possibilities \( m \) absent and \( m \) present, and further re-express the probability that \( m \) is present in terms of the probability that it is characterized by the particular \( \mu \):

\[ P(g) = P(g|0)P(0) + P(g|m)P(m) \]
\[ = P(g|0)P(0) + P(m) \int d^N \mu p(\mu)P[g|m(\mu)], \quad (2.5) \]

where

\[ P(0) \equiv \begin{pmatrix} \text{The a priori probability} \\ \text{that the signal is not present.} \end{pmatrix}, \quad (2.6a) \]

\[ P(g|0) \equiv \begin{pmatrix} \text{The probability density of} \\ \text{observing } g(t) \text{ in the absence} \\ \text{of the signal.} \end{pmatrix}, \quad (2.6b) \]

\[ P[g|m(\mu)] \equiv \begin{pmatrix} \text{The probability density of} \\ \text{observing } g(t) \text{ assuming} \\ m(t; \mu) \text{ with particular} \end{pmatrix} \]
\[ \quad \text{\( \mu \) is present.}, \quad (2.6c) \]

\[ p(\mu) \equiv \begin{pmatrix} \text{The a priori probability} \\ \text{density that } m(t) \text{ is} \end{pmatrix} \]
\[ \quad \text{characterized by } \mu. \quad (2.6d) \]
Combining equations 2.3 and 2.5, we find

\[ P(m|g) = \frac{\Lambda}{\Lambda + P(0)/P(m)}, \]  

(2.7)

where

\[ \Lambda \equiv \int d^N\mu \Lambda(\mu) \]  

(2.8)

\[ \Lambda(\mu) \equiv p(\mu) \frac{P[g|m(\mu)]}{P(g|0)}. \]  

(2.9)

In equation 2.7 all of the dependence of \( P(m|g) \) on the data stream \( g \) has been gathered into the likelihood ratio \( \Lambda \). Aside from \( \Lambda \), \( P(m|g) \) depends only on the ratio of the \( a \ priori \) probabilities \( P(0) \) and \( P(m) \). In turn, the likelihood ratio depends on two components: the \( a \ priori \) probability density \( p(m|\mu) \) and the ratio \( P[g|m(\mu)]/P(g|0) \).

In order to determine \( P(m|g) \) we must assess the \( a \ priori \) probabilities and calculate the likelihood ratio. It is often the case that we know, or can make an educated guess regarding, the \( a \ priori \) probabilities. For example, the sources may be Poisson distributed in time [determining \( P(0) \) and \( P(m) \)], and they may be homogeneously distributed in space [determining \( p(r) \propto r^2 \), where \( r \) is the distance to the source]. At other times our assessment may be more subjective or based on imperfect knowledge, and in this case we can use the observed distribution of \( \mu \) to test the validity of our assessments using the techniques of hypothesis testing (Winkler \[8\] §7).

Now turn to the evaluation of \( P[g|m(\mu)]/P(g|0) \). To determine this ratio, first note that the conditional probability of measuring \( g(t) \) if the particular signal \( m(t;\mu) \) is present is the same as the conditional probability of measuring \( g'(t) = g(t) - m(t;\mu) \), assuming that the signal \( m(t;\mu) \) is not present in \( g' \):

\[ P[g|m(\mu)] = P[g - m(\mu)|0]. \]  

(2.10)

Consequently, we can focus on the conditional probability of measuring a data stream \( g(t) \) under the assumption that no signal is present \([P(g|0)]\).

In the absence of the signal, \( g(t) \) is simply an instance of \( n(t) \). Assume that the \( n(t) \) is a normal process with zero mean, characterized by the correlation function \( C_n(\tau) \) [or,
equivalently, by the one-sided power spectral density (PSD) \( S_n(f) \). In order to compute the ratio \( P[g|m(\mu)]/P(g|0) \), consider the continuum limit of the case of discretely sampled data \( \{g_i : i = 1, \ldots, N\} \), with the correspondence

\[
\begin{align*}
g_i &= g(t_i), \\
t_i - t_j &= (i - j)\Delta t, \\
\Delta t &= \frac{T}{N - 1}.
\end{align*}
\] (2.11a, 2.11b, 2.11c)

The probability that an individual \( g_i \) is a sampling of the random process \( n(t) \) is given by

\[
P(g_i|0) = \exp\left[ -\frac{1}{2} \frac{g_i^2}{\Delta t C_n(0)} \right] [2\pi C_n(0)]^{1/2}
\] (2.12)

and the probability that the ordered set \( \{g_i : i = 1, \ldots, N\} \) is a sampling of \( n(t) \) is

\[
P(g|0) = \exp\left[ -\frac{1}{2} \sum_{j,k=1}^{N} C_{jk}^{-1} g_j g_k \right] \left[ (2\pi)^N \det |C_{n,ij}| \right]^{1/2}
\] (2.13)

where \( C_{jk}^{-1} \) is defined by

\[
\delta_{jk} \equiv \sum_{l} C_{n,jl} C_{lk}^{-1}
\] (2.14)

and

\[
C_{n,ij} \equiv C_n [(i - j) \Delta t]
\] (2.15)

(Mathews & Walker [9] §14-6, Wainstein & Zubakov [7] eqn. 31.11). Note that the normalization constant in the denominator of equation (2.13) is independent of the \( g_i \); consequently, it does not affect the ratio \( P[g|m(\mu)]/P(g|0) \). Since it is this ratio that we are interested in, without loss of generality drop the normalization constant from the following.

To evaluate equation (2.13) in the continuum limit, first note that

\[
\delta(t_j - t_k) = \lim_{\Delta t \to 0} \frac{1}{\Delta t} \delta_{jk}.
\] (2.16)

Consequently,
\[ e^{2\pi if t_k} = \sum_j e^{2\pi if t_j} \delta_{jk} \]
\[ = \lim_{\Delta t \to 0} \frac{1}{\Delta t^2} \sum_j \Delta t e^{2\pi if t_j} \sum_l \Delta t C_n(t_j - t_l)C^{-1}(t_l, t_k) \]
\[ = \lim_{\Delta t \to 0} \frac{1}{\Delta t^2} \int_{-\infty}^\infty dt_j e^{2\pi if t_j} \int_{-\infty}^\infty dt_l C_n(t_j - t_l)C^{-1}(t_l, t_k) \]
\[ = \lim_{\Delta t \to 0} \frac{1}{\Delta t^2} \int_{-\infty}^\infty dt_l e^{2\pi if t_l} C^{-1}(t_l, t_k) \int_{-\infty}^\infty d\tau e^{2\pi if \tau} C_n(\tau) \quad (2.17a) \]
\[ = \lim_{\Delta t \to 0} \frac{1}{\Delta t^2} 2S_n(f)\widetilde{C}^{-1}(f, t_k). \quad (2.17b) \]

To proceed from equation 2.17a to 2.17b, use the Wiener-Khintchine (cf. Kittel \[10\] §28) theorem to relate the PSD \( S_n(f) \) to the correlation function \( C_n(\tau) \) and define
\[ \widetilde{C}^{-1}(f, t_k) \equiv \int_{-\infty}^\infty dt C^{-1}(t, t_k) e^{2\pi if t}. \quad (2.18) \]

Consequently, as we approach the continuum limit, we have
\[ \widetilde{C}^{-1}(f, t_k) = \lim_{\Delta t \to 0} \Delta t^2 \frac{2e^{2\pi if t_k}}{S_n(f)}. \quad (2.19) \]

With \( \widetilde{C}^{-1} \) and Parseval’s Theorem, we can evaluate the continuum limit of the argument of the exponential in equation 2.13:
\[ \lim_{\Delta t \to 0} \sum_{j,k=1}^N C^{-1}_{jk} g_j g_k = \lim_{\Delta t \to 0} \frac{1}{\Delta t^2} \sum_{j,k=1}^N \Delta t^2 C^{-1}(t_j, t_k)g(t_j)g(t_k) \]
\[ = \lim_{\Delta t \to 0} \frac{1}{\Delta t^2} \int_{-\infty}^\infty dt_j dt_k C^{-1}(t_j, t_k)g(t_j)g(t_k) \]
\[ = \lim_{\Delta t \to 0} \frac{1}{\Delta t^2} \int_{-\infty}^\infty df dt_k \widetilde{C}^{-1}(f, t_k)\tilde{g}^*(f)g(t_k) \]
\[ = 2 \int_{-\infty}^\infty df \frac{\tilde{g}^*(f)}{S_n(|f|)} \int_{-\infty}^\infty dt_k e^{2\pi if t_k}g(t_k) \]
\[ = 2 \int_{-\infty}^\infty df \frac{\tilde{g}(f)\tilde{g}^*(f)}{S_n(|f|)}. \quad (2.20) \]

Here and henceforth we will denote the Fourier transform of \( r(t) \) as \( \tilde{r}(f) \).

Since the detector output \( g(t) \) is real, \( \tilde{g}^*(f) = \tilde{g}(-f) \). Define the symmetric inner product \( \langle g, h \rangle \)
\[ \langle g, h \rangle \equiv \int_{-\infty}^\infty df \frac{\tilde{g}(f)\tilde{h}^*(f)}{S_n(|f|)}. \quad (2.21) \]
for real functions $g$ and $h$. In terms of this inner product,

\[
\Lambda(\mu) = p(\mu) \frac{P[g|m(\mu)]}{P(g|0)} = p(\mu) \exp \left[ 2 \langle g, m(\mu) \rangle - \langle m(\mu), m(\mu) \rangle \right],
\]

(2.22)

The likelihood ratio $\Lambda$ is found by substituting eqn. 2.22 into eqn. 2.8.

To summarize, the probability $P(m|g)$ that a signal of the class $m(t; \mu)$ is present in the output of the detector $g(t)$ can be expressed in terms of three a priori probabilities $[P(0), P(m), p(\mu)]$ and the ratio of two conditional probabilities $[P(m|g)/P(0|g)]$. The a priori probabilities must be assessed, while the ratio of the conditional probabilities can be calculated. Often we know, or can make an educated guess regarding, the a priori probabilities; at other times our assessment is subjective or otherwise based on imperfect knowledge. Finally we establish a threshold for $P(m|g)$ [or, equivalently, for $\Lambda$, $\ln \Lambda$, or some other surrogate of $P(m|g)$], and say that if the $P(m|g)$ (or its surrogate) exceeds the threshold then we have detected the signal.

I will not discuss detection further, except to say that the choice of threshold is influenced by our strategy to minimize errors. The two kinds of errors we can make are to claim the presence of a signal when one is in fact not present (a “false alarm”), or to dismiss an observed $g(t)$ as noise when a signal is present (a “false dismissal”). In order to minimize the probability of a false alarm (conventionally denoted $\alpha$) we want a large threshold, while to minimize the probability of a false dismissal (conventionally denoted $\beta$) we want a small threshold. One obvious strategy for choosing the threshold is to minimize the sum $\alpha + \beta$, i.e., to minimize the probability of making an error. Alternatively, some other combination of $\alpha$ and $\beta$ may be minimized, taking into account the relative seriousness of the different kinds of errors. Regardless, it is inadvisable to blindly choose a threshold for $P(m|g)$ without careful consideration of the false alarm and false dismissal probabilities that arise and their relative severity.
B. Measurement

Turn now to the question of measurement. From equations 2.3, 2.5 and 2.9 we have

\[
p[m(\mu)|g] = \begin{cases} 
\text{The conditional probability that} \\
\text{the particular signal } m(t; \mu) \text{ is} \\
\text{present in the data stream } g(t). 
\end{cases} 
= \frac{\Lambda(\mu)}{\Lambda + P(0)/P(m)}. 
\](2.23)

This conditional probability density is directly proportional to \(\Lambda(\mu)\) and, since the denominator in equation 2.23 is independent of \(\mu\), it is maximized where \(\Lambda(\mu)\) is maximized. If we assume that the signal is present, then the probability density that it is characterized by \(\mu\) is

\[
p[m(\mu)|g, m] = \frac{\Lambda(\mu)}{\Lambda}. 
\](2.24)

The goal of the measurement process is to determine a volume \(V(P)\) in parameter space such that \(\mu \in V(P)\) with probability \(P\). This volume is “centered” on the mode of the distribution \(p[m(\mu)|g]\) in a way we define later on. The mode of either \(p[m(\mu)|g]\) or \(p[m(\mu)|g, m]\) is the \(\mu\) that maximizes \(\Lambda(\mu)\). Denote the mode by \(\hat{\mu}\). While I will occasionally refer to \(\hat{\mu}\) as the “measured” parameterization of the signal, bear in mind that \(\hat{\mu}\) is only the most likely parameterization of the observed signal.

If we assume that the global maximum of \(\Lambda(\mu)\) is also a local extremum, then \(\hat{\mu}\) satisfies

\[
0 = \frac{\partial \Lambda(\mu)}{\partial \mu_i}; 
\](2.25)

equivalently, \(\hat{\mu}\) maximizes

\[
\ln \Lambda(\mu) = \ln p(\mu) + 2 \langle m(\mu), g \rangle - \langle m(\mu), m(\mu) \rangle, 
\](2.26)

While we assume in what follows that the distribution has a single mode, the generalization to a multi-modal distribution is trivial.
\[ \partial \ln p(\hat{\mu}) \partial \mu_i = 0 + 2 \left( \partial m(\hat{\mu}), g - m(\hat{\mu}) \right). \tag{2.27} \]

This final set of equations is in general non-linear and may be satisfied by several different \( \mu \). Some will represent local maxima, while others will correspond to local minima or inflection points; thus, equation 2.25 is a necessary but not sufficient condition for \( \hat{\mu} \).

An important characterization of the strength of the signal in a detector is the signal-to-noise ratio (SNR). The “actual” SNR depends on the true parameterization of the signal \( \tilde{\mu} \). We do not have access to \( \tilde{\mu} \); however, we do know that the most likely value of \( \tilde{\mu} \) is \( \hat{\mu} \), and we define the SNR in terms of \( \hat{\mu} \):

\[ \rho^2 = 2 \langle m(\hat{\mu}), m(\hat{\mu}) \rangle. \tag{2.28} \]

The factor of two arises because the power spectral density \( S_n(f) \) is one-sided while \( \tilde{m}(f) \) is two-sided. Note that \( \rho^2 \) is expressed in terms of the signal power (i.e., it is proportional to the square of the signal amplitude). There is some ambiguity in the literature over whether “SNR” refers to \( \rho \) or \( \rho^2 \). We avoid the ambiguity by referring to either \( \rho \) or \( \rho^2 \) wherever the context demands it.

Having found the distribution \( p[m(\mu)|g] \) (or \( p[m(\mu)|g,m] \)), we define the boundary of the volumes \( V(P) \) to be its iso-surfaces. The probability \( P \) corresponding to the iso-surface \( p[m(\mu)|g,m] = K^2 \) is

\[ P = \int_{p[m(\mu)|g,m] \geq K^2} d^N \mu p[m(\mu)|g]. \tag{2.29} \]

Note that since the distribution \( p[m(\mu)|g,m] \) is not generally symmetric, \( \hat{\mu} \) is not necessarily the mean of \( \mu \). Also, if the distribution \( p[m(\mu)|g] \) has more than one local maximum then \( V(P) \) need not be simply connected.

To summarize, suppose we have an observation \( g(t) \) which we assume (or conclude) includes a signal \( m(\tilde{\mu}) \) (for unknown \( \tilde{\mu} \)). We construct the probability density \( p[m(\mu)|g,m] \) according to equation 2.24, and identify iso-surfaces of \( p[m(\mu)|g,m] \) as the boundary of
probability volumes $V(P)$ according to equation 2.29. Finally, we assert that $\tilde{\mu} \in V(P)$ with probability $P$.

III. MEASUREMENT SENSITIVITY

In §II we saw how to decide whether a signal is present or absent from the output of a noisy detector, and, if present, how to determine bounds on the parameterization of the signal. Now I show how to anticipate the precision with which a detector can place bounds on the parameterization that characterizes a signal. In particular, consider an observed $g(t)$ which contains a signal $m(t; \mu)$ for unknown $\tilde{\mu}$. We are interested ultimately in the distribution of

$$\delta \mu \equiv \tilde{\mu} - \hat{\mu}$$

(3.1)

where $\tilde{\mu}$ is determined by the techniques discussed in §II. There are an infinity of possible $g(t)$ that can lead to the same $\tilde{\mu}$ [corresponding to different instances of the noise $n(t)$], and for each there is a different probability distribution $p[m(\mu)|g]$ (cf. eqn. 2.23) and a different set of probability volumes $V(P)$. We will find the probability volumes $V(P)$ corresponding to

$$p(\tilde{\mu}|\hat{\mu}) = \left( \begin{array}{c} \text{The conditional probability density} \\ \text{that the signal parameterization is} \\ \tilde{\mu}, \\ \text{assuming that the mode of the} \\ \text{distribution } p[m(\mu)|g] \text{ is } \tilde{\mu}. \end{array} \right)$$

(3.2)

I show first how to do this exactly, and then show a useful approximation for strong signals.

The mode $\hat{\mu}$ of the distribution $p[m(\mu)|g, m]$ satisfies

$$2 \left\langle m(\tilde{\mu}) - m(\hat{\mu}), \frac{\partial m}{\partial \mu_j}(\hat{\mu}) \right\rangle + \frac{\partial \ln p}{\partial \mu_j}(\hat{\mu}) = -2 \left\langle n, \frac{\partial m}{\partial \mu_j}(\hat{\mu}) \right\rangle$$

(3.3)
Since \( n(t) \) is a normal variable with zero mean, so are each of the \( \langle n, \partial m/\partial \mu_j \rangle \) on the righthand side of equation 3.3. Denote these random variables \( \nu_i \):

\[
\nu_i \equiv 2 \left\langle n, \frac{\partial m}{\partial \mu_i} (\hat{\mu}) \right\rangle. \tag{3.4}
\]

The joint distribution of the \( \nu_i \) is a multivariate Gaussian and its properties determine, through the equation 3.3, the properties of the distribution of \( \delta \mu \). Consequently we can focus on the joint distribution of the \( \nu_i \).

Since the \( \nu_i \) are normal, their distribution is determined completely by the means \( \nu_i \), which vanish, and the quadratic moments

\[
\mathcal{M} = 4 \left\langle n, \frac{\partial m}{\partial \mu_i} (\hat{\mu}) \right\rangle \left\langle n, \frac{\partial m}{\partial \mu_j} (\hat{\mu}) \right\rangle. \tag{3.5}
\]

To evaluate the average on the righthand side, we will use the ergodic principle to turn the ensemble average over the random process \( n \) into a time average over a particular instance of \( n \). Recalling that a time translation affects the Fourier transform of a function by a change in phase,

\[
\mathcal{F} [r(t+\tau)] = e^{-2\pi i f \tau} \mathcal{F} [r(t)], \tag{3.6}
\]

write

\[
\langle n(t+\tau), r(t) \rangle = \int_{-\infty}^{\infty} dt \, e^{-2\pi i f \tau} \frac{\tilde{n}(f) \tilde{r}^*(f)}{S_n(f)}. \tag{3.7}
\]

Consequently,

\[
\langle n, r \rangle \langle n, s \rangle = \lim_{T \to \infty} \frac{1}{2T} \int_{-T}^{T} d\tau \, \langle n(t+\tau), r \rangle \langle n(t+\tau), s \rangle
\]
\[
= \lim_{T \to \infty} \frac{1}{2T} \int_{-T}^{T} d\tau \int_{-\infty}^{\infty} df \, \frac{\tilde{n}(f) \tilde{r}^*(f)}{S_n(f)} e^{-2\pi i f \tau} \int_{-\infty}^{\infty} df' \frac{\tilde{n}(f') \tilde{s}^*(f')}{S_n(f')} e^{-2\pi i f' \tau}
\]
\[
= \lim_{T \to \infty} \frac{1}{2T} \int_{-\infty}^{\infty} df \, \frac{\tilde{n}(f) \tilde{r}^*(f)}{S_n(f)} \int_{-\infty}^{\infty} df' \frac{\tilde{n}(f') \tilde{s}^*(f')}{S_n(f')}, \tag{3.8a}
\]
\[
= \frac{1}{2} \int_{-\infty}^{\infty} df \frac{\tilde{r}^*(f) \tilde{s}^*(f)}{S_n(f)}, \tag{3.8b}
\]
\[
= \frac{1}{2} \langle r, s \rangle. \tag{3.8c}
\]
In going from eqn. 3.8a to eqn. 3.8b, we used the definition of the PSD of the detector noise $n(t)$:

$$S_n(f) \equiv \lim_{T \to \infty} \frac{1}{T} |\tilde{n}(f)|^2$$  \hfill (3.9)

(cf. Kittel [10] §28). With the result in equation 3.8c, we have

$$\nu_i \nu_j = 4 \langle n, \frac{\partial m}{\partial \mu_i}(\hat{\mu}) \rangle \langle n, \frac{\partial m}{\partial \mu_j}(\hat{\mu}) \rangle$$  \hfill (3.10a)

$$\equiv C^{-1}_{ij}. \hfill (3.10b)$$

In terms of the $C_{ij}$ (i.e., the inverse of the $C^{-1}_{ij}$), the joint distribution of the $\nu_i$ is given by

$$p(\nu) = \frac{\exp \left[ -\frac{1}{2} \sum_{i,j} C_{ij} \nu_i \nu_j \right]}{\left(2\pi\right)^N \det ||C_{ij}^{-1}||^{1/2}}$$  \hfill (3.11)

This is also the joint distribution of the quantities

$$- 2 \left\langle m(\bar{\mu}) - m(\hat{\mu}), \frac{\partial m}{\partial \mu_j}(\hat{\mu}) \right\rangle - \frac{\partial \ln p}{\partial \mu_j}(\hat{\mu})$$  \hfill (3.12)

that appear on the lefthand side of equation 3.3; consequently, we expect that for an observation characterized by a given $\hat{\mu}$ the probability volumes $V(P)$ are given implicitly by

$$K^2 \geq \sum_{i,j} C_{ij} \left[ 2 \left\langle m(\bar{\mu}) - m(\hat{\mu}), \frac{\partial m}{\partial \mu_i}(\hat{\mu}) \right\rangle + \frac{\partial \ln p}{\partial \mu_i}(\hat{\mu}) \right]$$

$$\times \left[ 2 \left\langle m(\bar{\mu}) - m(\hat{\mu}), \frac{\partial m}{\partial \mu_j}(\hat{\mu}) \right\rangle + \frac{\partial \ln p}{\partial \mu_j}(\hat{\mu}) \right]$$  \hfill (3.13)

where

$$P = \int_{\sum_{i,j} C_{ij} \nu_i \nu_j \leq K^2} d^N \nu \frac{\exp \left[ -\frac{1}{2} \sum_{i,j} C_{ij} \nu_i \nu_j \right]}{\left(2\pi\right)^N \det ||C_{ij}^{-1}||^{1/2}}.$$  \hfill (3.14)

This result is exact as long as the maximum $\hat{\mu}$ of $\Lambda(\mu)$ is also a local extremum of $\Lambda(\mu)$.

As the SNR becomes large the distribution $p(\tilde{\mu} | \hat{\mu})$ becomes sharply peaked about $\hat{\mu}$ and the determination of the volume $V(P)$ is greatly simplified. Suppose that $\rho^2$ is so large that
for $\bar{\mu} \in V(P)$ for all $P$ of interest, the difference $m(\bar{\mu}) - m(\hat{\mu})$ can be linearized in $\delta \mu$. We then obtain in place of equation 3.3

$$
\sum_i \delta \mu_i C_{ij}^{-1} = -2 \left< n, \frac{\partial m}{\partial \mu_j}(\bar{\mu}) \right> - \frac{\partial \ln p}{\partial \mu_j}(\bar{\mu})
$$

(3.15)

The random variables $\delta \mu$ are related to the $\nu$ by a linear transformation,

$$
\delta \mu_i = -\sum_j C_{ij} \left[ \nu_j + \frac{\partial \ln p}{\partial \mu_j}(\bar{\mu}) \right];
$$

(3.16)

consequently, the $\delta \mu$ are normal with means

$$
\overline{\delta \mu_i} = -\sum_j C_{ij} \frac{\partial \ln p}{\partial \mu_j}(\bar{\mu}),
$$

(3.17)

and quadratic moments

$$
(\delta \mu_i - \overline{\delta \mu_i})(\delta \mu_j - \overline{\delta \mu_j}) = C_{ij}.
$$

(3.18)

The probability distribution $p(\delta \mu | \mu)$ is a multivariate Gaussian (cf. eqn. 3.11):

$$
p(\delta \mu | \mu) = \exp \left[ -\frac{1}{2} \sum_{i,j} C_{ij}^{-1} \left( \delta \mu_i - \overline{\delta \mu_i} \right) \left( \delta \mu_j - \overline{\delta \mu_j} \right) \right] \\
\left[ (2\pi)^N \det |C_{ij}| \right]^{1/2}.
$$

(3.19)

Note that the matrix $C_{ij}$ now has acquired a physical meaning: in particular, we see that the variances $\sigma_i^2$ of the $\delta \mu_i$ are

$$
\sigma_i^2 \equiv (\overline{\delta \mu_i} - \overline{\delta \mu_i})^2 = C_{ii}
$$

(3.20)

and the correlation coefficients $r_{ij}$ are given by

$$
r_{ij} \equiv \frac{C_{ij}}{\sigma_i \sigma_j}
$$

(3.21)

In this sense we say that $C_{ij}$ is the covariance matrix of the random variables $\delta \mu$.

In the strong signal approximation, the surfaces bounding the volume $V(P)$ are ellipsoids defined by the equation
\[ \sum_{i,j} (\delta \mu_i - \overline{\delta \mu_i}) (\delta \mu_j - \overline{\delta \mu_j}) C_{ij}^{-1} = K^2, \tag{3.22} \]

where the constant \( K^2 \) is related to \( P \) by

\[ P = \int \sum_{i,j} C_{ij}^{-1} x^i x^j \leq K^2 \]

\[ \exp \left[ -\frac{1}{2} \sum_{i,j} C_{ij}^{-1} x^i x^j \right] \left[ (2\pi)^N \det ||C_{ij}|| \right]^{1/2} \tag{3.23} \]

It is often the case that not all of the parameters that characterize the signal are of physical interest. In that case, we may integrate the probability distribution (eqn. 3.11 or 3.19) over the uninteresting parameters, leaving a distribution describing just the parameters of physical interest.

Finally we come to the question of when the linearization in equation 3.15 is a reasonable approximation. Two considerations enter here:

1. It is important that the probability contours of interest (e.g., 90\%) do not involve \( \delta \mu \) so large that the linearization of \( m(\bar{\mu}) - m(\hat{\mu}) \) is a poor approximation; and

2. It is important that the condition number (cf. Golub & Van Loan [11]) of the matrix \( C_{ij}^{-1} \) be sufficiently small that the inverse \( C_{ij} \) is insensitive to this approximation in the neighborhood of \( \hat{\mu} \).

These two conditions will depend on the problem addressed. If the validity of the linearization procedure is doubtful owing to the violation of either or both of these conditions, then we must fall-back on equation 3.3 and the exact results in equations 3.13 and 3.14.

**IV. APPLICATION: A PERTURBED BLACK HOLE**

In this section, I show how to use the approximate techniques developed in §III to find the precision with which the mass and angular momentum of a perturbed black hole can be

\[ ^2 \text{Recall that the relative error in } \delta \mu \text{ is the condition number times the relative error in } C_{ij}^{-1}: \text{ for a large condition number, small errors in } C_{ij}^{-1} \text{ introduced by the linearization approximation can result in large errors in } \delta \mu. \]
determined through measurement in an interferometric gravitational wave detector. This problem was first considered by Echeverria [5].

Consider a single interferometric gravitational wave detector and a perturbed black hole of mass $M$ and dimensionless angular momentum parameter $a$. Focus attention on a single oscillation mode of the black hole, e.g., the $l = m = 2$ mode. The strain measured by the detector has the time dependence of an exponentially damped sinusoid characterized by the four parameters $Q$, $f$, $V$, and $T$:

$$h(t) = \begin{cases} 
0 & \text{for } t < 0, \\
V^{-1/3} e^{-f(t-T)/Q} \sin [2\pi f(t-T)] & \text{for } t > 0.
\end{cases}$$

(4.1)

For convenience, assume that the perturbation begins abruptly at the starting time $T$. The frequency $f$ depends inversely on the mass of the black hole, and has a weak dependence on its angular momentum: for the $l = m = 2$ quasi-normal oscillation mode,

$$f \simeq \frac{F(a)}{2\pi M}$$

(4.2a)

$$F(a) \equiv 1 - \frac{63}{100} (1 - a)^{3/10},$$

(4.2b)

is an accurate semi-empirical expression for the real part of the quasi-normal mode frequency (Echeverria [5] eqn. 4.4 and tbl. II). The quality $Q$ is the damping time $\tau$ measured in units of the frequency $f$:

$$Q = \pi f \tau.$$  

(4.3)

For the $l = m = 2$ oscillation mode of the black hole, $Q$ depends entirely on $a$:

$$Q \simeq Q(a) \equiv 2(1 - a)^{-9/20}$$

(4.4)

(Echeverria [5] eqn. 4.3 and tbl. II). Finally, the amplitude $V^{-1/3}$ of the waveform depends on the distance to the source, the size of the perturbation, and the relative orientation of the detector and the source.

This peculiar parameterization of the amplitude reflects our expectation that perturbed black holes are distributed uniformly throughout space (i.e., $V \propto r^3$) and that all relative
orientations of the detector and the black hole source are equally probable. Additionally, it reflects an assumption that perturbations of any allowed amplitude are equally probable; consequently, the a priori distribution $p(V)$ is uniform. Let us also assume that $p(a)$, $p(f)$ and $p(T)$ are uniform and that there is no a priori correlation of $a$, $f$, $V$, or $T$.

An interferometric gravitational wave detector is naturally a broadband receiver, though it can be operated in a narrow band mode (cf. Vinet, Meers, Man, & Brillet [12], Meers [13] and Krolak, Lobo & Meers [14]). Assume that the detector response function is uniform in the frequency domain over the bandwidth of the gravitational wave; consequently, the signal component in the output of the detector $[m(t, \mu)]$ is equal to the waveform $h(t; Q, f, V, T)$ (cf. eqn. 4.1). Assume also that the noise PSD ($S_n$) of the detector is independent of frequency ($f$) in the bandwidth $(1/\tau)$ of the signal (I will discuss the validity of this approximation below).

**A. The signal-to-noise ratio**

As a first step toward finding the precision with which $a$, $M$, $V$ and $T$ can be determined, we calculate the SNR $\rho^2$. With $h$ given by equation 4.1, evaluate $\rho^2$ using equation 2.28 to obtain

$$\rho^2 = \frac{2Q^3}{\pi f V^{2/3}(1 + 4Q^2)S_n}.$$  \hspace{1cm} (4.5)

This expression is valid to better than a percent as long as the signal is observed for a period of time $\Delta t \gtrsim 2.5\tau$.

In arriving at equation 4.3 we assumed that the noise PSD is constant over the bandwidth of the signal so that $S_n = S_h(f)$. The signal bandwidth $\Delta f$ is approximately

$$\Delta f \simeq \frac{1}{\tau} = \frac{\pi}{2} (1 - a)^{9/20} f.$$  \hspace{1cm} (4.6)

For small $a$ the bandwidth is approximately $f$, while for large $a$ the signal is monochromatic. For small $a$ the approximation that $S_n$ is constant over the bandwidth of the signal is only
a fair approximation for LIGO (cf. Vogt [1], Abramovici et al. [2]) or LAGOS (cf. Faller et al. [4]); however, it becomes a good approximation for both detectors when $a \gtrsim 0.9$ (corresponding to $\Delta f/f \lesssim 1/2$).

The amplitude $V$ depends on the detector orientation with respect to the black hole, the amplitude of the perturbation, and the distance between the black hole and the detector. Average $\rho^2$ over all possible orientations of the detector with respect to the black hole (cf. Thorne [15] §9.5.3) to obtain

$$\overline{\rho^2} = \frac{16}{5} \frac{Q^2}{F^2 (1 + 4Q^2)} \frac{\epsilon M}{S_n} \left( \frac{M}{r} \right)^2$$

where $\epsilon M$ is the total energy radiated by the $l = m = 2$ mode of the black hole perturbation and $r$ is the distance of the source.

When operated as a broadband detector, the LIGO advanced detectors will be most sensitive to perturbed black holes with $50 M_\odot \lesssim M \lesssim 100 M_\odot$ where $S_n \simeq 10^{-48} \text{ Hz}^{-1}$ (cf. Krolak, Lobo & Meers [14], Dhurandhar, Krolak & Lobo [16], Vogt et al. [1], Abramovici et al. [2]). LAGOS will be most sensitive to perturbed black holes in the range $10^6 M_\odot \lesssim M \lesssim 10^7 M_\odot$, where $S_n \simeq 10^{-42} \text{ Hz}^{-1}$ (cf. Faller et al. [4]). Consequently

$$\overline{\rho^2}^{1/2} \simeq 5.8G(a) \left\{ \begin{array}{c} \left( \frac{\epsilon}{4 \times 10^{-10}} \right)^{1/2} \left( \frac{3 \text{ Mpc}}{r} \right) \left( \frac{M}{50 M_\odot} \right)^{3/2} \left( \frac{10^{-48} \text{ Hz}^{-1}}{S_n} \right)^{1/2} \quad \text{LIGO} \\ \left( \frac{\epsilon}{5 \times 10^{-12}} \right)^{1/2} \left( \frac{3 \text{ Gpc}}{r} \right) \left( \frac{M}{10^7 M_\odot} \right)^{3/2} \left( \frac{10^{-42} \text{ Hz}^{-1}}{S_n} \right)^{1/2} \quad \text{LAGOS} \end{array} \right.$$  

where

$$G(a) \equiv \frac{37}{200} \left[ \frac{17Q^2}{F^2 (1 + 4Q^2)} \right]^{1/2} .$$

For frequencies outside of the range 100 Hz to 200 Hz, the LIGO PSD $S_n$ scales with frequency: for frequencies greater than approximately 200 Hz (corresponding to $M \lesssim 50 M_\odot$), $S_n$ scales as $f^2$ (cf. Thorne [15], Krolak, Lobo & Meers [14]), and for frequencies less than 100 Hz ($M \gtrsim 100 M_\odot$) it scales as $f^{-4}$ (cf. Dhurandhar, Krolak, & Lobo [16]). Similarly, for frequencies outside the range $10^{-3}$ Hz to $10^{-2}$ Hz the LAGOS PSD $S_n$ scales with frequency: for $f \gtrsim 10^{-2}$ Hz it scales as $f^2$, and for $f \lesssim 10^{-3}$ Hz it scales as $f^{-4}$ (cf. Faller et al. [4]). Consequently
\[ \rho^2 \propto \begin{cases} M^{-1} & M \gtrsim 100 \, M_\odot \\ M^5 & M \lesssim 50 \, M_\odot \end{cases} \] (4.10)

for LIGO and

\[ \rho^2 \propto \begin{cases} M^{-1} & M \gtrsim 10^7 \, M_\odot \\ M^5 & M \lesssim 10^6 \, M_\odot \end{cases} \] (4.11)

for LAGOS.

Little is known about the rate of, or the energy radiated during, black hole formation (cf. Rees [17], Kochanek, Shapiro & Teukolsky [18]); however, owing to the extreme sensitivity of both the LAGOS and LIGO detectors, it seems a conservative estimate that the formation of a black hole of mass \(10^6 \, M_\odot \lesssim M \lesssim 10^7 \, M_\odot\) anywhere in the universe will be detectable by LAGOS, and the formation of black holes with \(50 \, M_\odot \lesssim M \lesssim 100 \, M_\odot\) will be observable in LIGO at least to the distance of the Virgo cluster (\(\sim 10\) Mpc). Additionally, note that the energy radiated in the \(l = 2\) mode during the radial infall of a test body (mass \(m\)) onto a Schwarzschild black hole (mass \(M\)) is given by

\[ \Delta E = \epsilon M \approx 10^{-2} \frac{m^2}{M}; \] (4.12)

(Davis, Ruffini, Press, & Price [19], Oohara & Nakamura [20]; similar results hold for Kerr black holes: Sasaki & Nakamura [21], Kojima & Nakamura [22]). Consequently, the capture of a solar mass compact object (e.g., a black hole or neutron star) onto a black hole of mass \(10^6 - 10^7 \, M_\odot\) (corresponding to \(\epsilon \approx 10^{-14} - 10^{-16}\)) may also be observable to a distance of 3 Mpc (cf. eqn. 4.8).

Figure 4 shows the factor \(G(a)\) (cf. eqn. 4.9) as a function of \(a\). This figure may also be regarded as a plot of \(\rho(a)\) for fixed \(M, \epsilon, r, S_n\), and detector-source orientation. With this interpretation, note how \(\rho\) decreases with increasing \(a\). The reason for this behavior is that at fixed \(M\), the frequency \(f\) and damping timescale \(\tau\) both increase with \(a\); consequently, a signal of smaller amplitude (i.e., smaller \(\rho^2\)) will yield the same radiated energy.
B. Precision of measurement

While the parameters $Q$ and $f$ are convenient for characterizing the detector response, it is the determination of $a$ and $M$ that is of direct physical interest. If the perturbed black hole is also observed electromagnetically (e.g., if it is the result of the gravitational collapse of a star in a type II supernova), then determination of $V$ and $T$ may also be interesting. Regardless, we are more interested in the covariance matrix for the parameters \{a, M, V, T\} than for the parameters \{Q, f, V, T\}. It turns out, however, that it is simpler to first determine the covariance matrix for the parameterization \{Q, f, V, T\}.

To find the covariance matrix for the parameterization \{a, M, V, T\}, first define the three dimensionless parameters $\tilde{\epsilon}', \tilde{\xi}'$ and $\tilde{\zeta}'$ by

\[
\begin{align*}
\tilde{\epsilon}' &\equiv \tilde{f} - \mathring{f}, \\
\tilde{\xi}' &\equiv \tilde{V} - \mathring{V}, \\
\tilde{\zeta}' &\equiv \hat{f} (\tilde{T} - \mathring{T}),
\end{align*}
\]

and evaluate $C_{ij}'^{-1}$ for the parameterization \{Q, $\epsilon'$, $\xi'$, $\zeta'$\}:

\[
\begin{pmatrix}
\langle \frac{\partial h}{\partial Q}, \frac{\partial h}{\partial f} \rangle f & \langle \frac{\partial h}{\partial Q}, \frac{\partial h}{\partial V} \rangle V & \langle \frac{\partial h}{\partial Q}, \frac{\partial h}{\partial T} \rangle \frac{1}{f} \\
\langle \frac{\partial h}{\partial f}, \frac{\partial h}{\partial f} \rangle f^2 & \langle \frac{\partial h}{\partial f}, \frac{\partial h}{\partial V} \rangle fV & \langle \frac{\partial h}{\partial f}, \frac{\partial h}{\partial T} \rangle \\
\langle \frac{\partial h}{\partial V}, \frac{\partial h}{\partial V} \rangle fV & \langle \frac{\partial h}{\partial V}, \frac{\partial h}{\partial T} \rangle V & \langle \frac{\partial h}{\partial T}, \frac{\partial h}{\partial T} \rangle \frac{1}{f^2}
\end{pmatrix}.
\]

The components of $C_{ij}'^{-1}$ appearing in equation 4.14 are

\[
\begin{align*}
\langle \frac{\partial h}{\partial Q}, \frac{\partial h}{\partial Q} \rangle &= \frac{3 + 6Q^2 + 8Q^4}{2Q^2 (1 + 4Q^2)^2 \rho^2}, \\
\langle \frac{\partial h}{\partial Q}, \frac{\partial h}{\partial f} \rangle f &= -\frac{3 + 4Q^2}{4Q (1 + 4Q^2) \rho^2}, \\
\langle \frac{\partial h}{\partial Q}, \frac{\partial h}{\partial V} \rangle V &= -\frac{3 + 4Q^2}{12Q (1 + 4Q^2) \rho^2}, \\
\langle \frac{\partial h}{\partial Q}, \frac{\partial h}{\partial T} \rangle \frac{1}{f} &= \frac{\pi \rho^2}{4Q^2}.
\end{align*}
\]
\[
\left\langle \frac{\partial h}{\partial f} , \frac{\partial h}{\partial f} \right\rangle f^2 = \left( \frac{1}{2} + Q^2 \right) \rho^2 \tag{4.15e}
\]
\[
\left\langle \frac{\partial h}{\partial f} , \frac{\partial h}{\partial V} \right\rangle fV = \frac{\rho^2}{12} \tag{4.15f}
\]
\[
\left\langle \frac{\partial h}{\partial f} , \frac{\partial h}{\partial T} \right\rangle = \frac{-\pi \rho^2 (1 + 4Q^2)}{4Q} \tag{4.15g}
\]
\[
\left\langle \frac{\partial h}{\partial V} , \frac{\partial h}{\partial V} \right\rangle V^2 = \frac{\rho^2}{18} \tag{4.15h}
\]
\[
\left\langle \frac{\partial h}{\partial V} , \frac{\partial h}{\partial T} \right\rangle \frac{V}{f} = 0 \tag{4.15i}
\]
\[
\left\langle \frac{\partial h}{\partial T} , \frac{\partial h}{\partial T} \right\rangle \frac{1}{f^2} = \frac{\pi \rho^2 (1 + 4Q^2)}{2Q^2}. \tag{4.15j}
\]

The components of the covariance matrix $C'_{ij}$ are

\[
C'_{QQ} = \frac{4Q^4 + 3A^2 + 1}{2Q^2 \rho^2} \tag{4.16a}
\]
\[
C'_{Q\xi} = \frac{1}{2Q^3 \rho^2} \tag{4.16b}
\]
\[
C'_{Q\zeta} = \frac{3(4Q^4 + 5Q^2 + 1)}{2Q^3 \rho^2} \tag{4.16c}
\]
\[
C'_{Q\epsilon} = -\frac{1}{2 \pi \rho^2} \tag{4.16d}
\]
\[
C'_{\epsilon\epsilon} = \frac{1 - 2Q^2 (1 - 4Q^2)}{2Q^4 (1 + 4Q^2) \rho^2} \tag{4.16e}
\]
\[
C'_{\epsilon\xi} = \frac{3 (1 - Q^2)}{2Q^4 \rho^2} \tag{4.16f}
\]
\[
C'_{\epsilon\zeta} = -\frac{1}{2 \pi \rho^2 Q (1 + 4Q^2)} \tag{4.16g}
\]
\[
C'_{\xi\xi} = \frac{9 (1 + 2Q^2)^2}{2Q^4 \rho^2} \tag{4.16h}
\]
\[
C'_{\xi\epsilon} = -\frac{3}{2 \pi Q \rho^2} \tag{4.16i}
\]
\[
C'_{\xi\zeta} = \frac{2Q^2}{\pi^2 (1 + 4Q^2) \rho^2}. \tag{4.16j}
\]

Now define the three dimensionless parameters $\epsilon$, $\xi$, and $\zeta$ by

\[
\hat{M} \epsilon \equiv \widetilde{M} - \hat{M} \tag{4.17a}
\]
\[
\hat{V} \xi \equiv \widetilde{V} - \hat{V} \tag{4.17b}
\]
\[
\hat{M} \zeta \equiv \widetilde{T} - \hat{T}. \tag{4.17c}
\]
The covariance matrix $C_{ij}$ for the parameterization \{a, \epsilon, \xi, \zeta\} is given in terms of $C'_{ij}$ by

$$C_{ij} = \sum_{k,l} J_{ik}^{-1} C'_{kl} J_{lj}^{-1},$$

where the symmetric matrix $J_{ij}$ is given by

$$J = \begin{pmatrix}
\frac{dQ}{da} & -\frac{1}{fM} \frac{df}{da} & 0 & 0 \\
-\frac{1}{fM} \frac{df}{da} & (fM)^2 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 0 & (fM)^2 & (fM)^2
\end{pmatrix}.$$ (4.19)

Like $C'_{ij}$, the matrix $C_{ij}$ is a function only of $\hat{a}$ and $\rho^2$, and has the elements

$$C_{aa} = \frac{(1 + 2Q^2)(1 + 4Q^2)}{2Q^2Q'^{2}} \frac{1}{\rho^2},$$ (4.20a)

$$C_{ee} = \left\{ \frac{[QF'(1 + 2Q^2)(1 + 4Q^2) - 2FQ']F'}{2Q^3Q'^{2}F^2} + \frac{1 - 2Q^2 + 8Q^4}{2Q^4(1 + 4Q^2)} \right\} \frac{1}{\rho^2},$$ (4.20b)

$$C_{\xi\xi} = \frac{9(1 + 2Q^2)^2}{2Q^4\rho^2},$$ (4.20c)

$$C_{\zeta\zeta} = \frac{8Q^2}{(1 + 4Q^2)F^2\rho^2},$$ (4.20d)

$$C_{ae} = \frac{Q(1 + 2Q^2)(1 + 4Q^2)F' - FQ'}{2FQ^3Q'^{2}\rho^2},$$ (4.20e)

$$C_{a\xi} = \frac{3(1 + 4Q^2)(1 + Q^2)}{2Q^3Q'^{2}\rho^2},$$ (4.20f)

$$C_{a\zeta} = -\left(FQ'\rho^2\right)^{-1},$$ (4.20g)

$$C_{e\xi} = \frac{3[Q(1 + Q^2)(1 + 4Q^2)F' + (Q^2 - 1)FQ']}{2Q^4FQ'^{2}\rho^2},$$ (4.20h)

$$C_{e\zeta} = \frac{(1 - 4Q^2)FQ' - Q(1 + 4Q^2)F'}{Q(1 + 4Q^2)F^2Q'^{2}\rho^2},$$ (4.20i)

$$C_{\xi\zeta} = -\frac{3}{QF\rho^2},$$ (4.20j)

where $F(a)$ and $Q(a)$ are given by equations 4.2b and 4.4. Finally, in terms of these coefficients, we have (cf. eqns. 3.21 and 3.21)
\[ \sigma^2_M = \hat{M}^2 \sigma^2_e \] (4.21a)

\[ \sigma^2_V = \hat{V}^2 \sigma^2_e \] (4.21b)

\[ \sigma^2_T = \hat{M}^2 \sigma^2_\xi \] (4.21c)

\[ r_{aM} = r_{ae} \] (4.21d)

\[ r_{aV} = r_{a\xi} \] (4.21e)

\[ r_{aT} = r_{a\xi} \] (4.21f)

\[ r_{MV} = r_{e\xi} \] (4.21g)

\[ r_{MT} = r_{e\xi} \] (4.21h)

\[ r_{VT} = r_{\xi\xi} \] (4.21i)

The results for the standard deviations \( \sigma_a \) and \( \sigma_M/M \) and correlation coefficient \( r_{aM} \) found semi-numerically in Echeverria [5] (his eqns. 4.10a–c and table II) are approximations to the analytic results found here in equations 4.20a, 4.21a and 4.21d. Additionally, we give analytic forms of the other variances and correlations coefficients.

Figure 2 shows \( \sigma_a, \sigma_M/M, \sigma_V/V, \sigma_T/M \) (eqns. 3.20, 4.20a–4.20d), normalized by \( \rho \) as shown, as functions of the measured \( a \). Note how for \( a \lesssim 0.8 \), the angular momentum parameter is determined less precisely than the mass. Figures 3a–c shows the six correlation coefficients (eqns. 3.21, 4.20e–4.20j) as functions of the measured \( a \). These are independent of \( \rho \). In figures 3a–c note how \( \delta a \) and \( \delta M \) are highly correlated so and are not statistically independent parameters: for a complete discussion of this point, see Echeverria §IV.

Figure 4 shows the standard deviations for fixed \( \rho \). It is also useful to consider these same quantities for fixed \( M, r, \epsilon \) and \( S_n \) as was done in equation 4.7 and figure 1. Defining \( \rho_0 \) by

\[ \rho = \rho_0 G(a), \] (4.22)

where \( G(a) \) is given in equation 4.9, figure 4 shows \( \sigma_a, \sigma_M/M, \sigma_V/V \) and \( \sigma_T/M \) normalized by \( \rho_0 \) (for LAGOS and LIGO, \( \rho_0 \) is given by equation 4.8) and as functions of \( a \). Note the
difference between figures 2 and 4: in the first case, the SNR is held constant while in the second the the energy of the perturbation is held constant. In the second case, the precision with which $a$ and $M$ can be determined does not increase as rapidly with $a$ as in the first case, the precision with which $T$ can be determined is independent of $a$, and the precision with which the amplitude can be determined decreases with increasing $a$.

The elements of $C^{-1}_{ij}$ fully determine the distribution $p[m(\mu)|g]$ and the volumes $V(P)$. Generally we will have no interest in $V$ and $T$, in which case we integrate the distribution over all $T$ and $V$ to find the two-dimensional distribution

$$p[m(a, M)|g] = \exp \left[ \frac{1}{2(1-r_{aM}^2)} \left( \frac{\Delta M}{\sigma_M} + \frac{\Delta a}{\sigma_a} - 2 \frac{\Delta a \Delta M r_{aM}}{\sigma_a \sigma_M} \right) \right]$$

$$\frac{2\pi \sigma_a \sigma_M (1 - r_{aM}^2)^{1/2}}{2\pi \sigma_a \sigma_M (1 - r_{aM}^2)^{1/2}}$$

(4.23)

where

$$\Delta M \equiv M - \hat{M}$$

(4.24a)

$$\Delta a \equiv a - \hat{a}.$$  

(4.24b)

V. DISCUSSION

The earlier results of Echeverria on the precision of measurement are restricted to the case of large $\rho$ where the distribution of $\delta \mu$ is well-approximated by a Gaussian, though there is no discussion of what constitutes a sufficiently large SNR. Additionally, those results do not provide any guidance for estimating the precision with which the amplitude of the signal can be measured. Finally, there is no clear connection drawn between the measurement of the $\hat{\mu}$, the estimates of $\delta \mu_i, \delta \mu_j$, and the probability that $|\hat{\mu} - \tilde{\mu}|^2 \leq \overline{\delta \mu^2}$. The restriction to strong signals is required because of the expansion of Echeverria’s expression for $\rho$ in a power-series about the “measured” parameters and also because the methods described fail to take into account prior knowledge about the distribution of the parameters [i.e., the
prior knowledge plays an important role when the distribution of the $\delta \mu$ is not uniform or the SNR is small.

On the other hand, the maximum likelihood analysis described in §II is applicable for all SNR (though the approximate techniques discussed at the end of §III are appropriate only when the distribution of the $\delta \mu$ is well-approximated by a Gaussian). It does not elevate any parameter to a special status: the amplitude of the signal and its precision are determined in the same way that all other signal parameters and their precision are determined. Finally, it gives clear meaning to the measured parameters $\hat{\mu}$ and the precision of measurement by providing the probability distribution of the $\delta \mu$.

A complete discussion of how the optimal filter techniques of Echeverria [5] are related to the maximum likelihood analysis presented here can be found in Echeverria & Finn [6].

VI. CONCLUSIONS

In the analysis of the results of an observation made in a detector, it is useful to distinguish between detection and measurement. The analysis involved in detection refers only to the presence or absence of a signal characterizing a particular class of sources to which the detector is sensitive (e.g., perturbed black holes). A particular source of this class is described by a set of parameters: e.g., among the parameters describing the signal from a perturbed black hole is the black hole mass and angular momentum. Detection addresses only whether a signal of this class is present in the observed output of the detector, and not the particular values of the parameters that best describe the signal.

Measurement follows detection: it refers to the determination of the values of the parameters that best characterize the particular signal assumed to be present in the detector output (it only makes sense to speak of measuring the parameters of a real signal). For example, once we have concluded that we have detected the signal from the formation of a black hole, then we can go on to measure the black hole mass and angular momentum.

In order to determine whether the observed output of a detector includes a signal from
a given class of sources, we saw how to calculate the probability that the detector output is consistent with the presence of the signal. That probability depends on the characteristics of the detector noise, the observed detector output, and a parameterized model of the detector response to the signal. In addition, it depends on several a priori probabilities that must be assessed. When the calculated probability exceeds a certain threshold then we say that the we have detected a signal. Setting the threshold requires careful consideration of the relative severity of falsely claiming a detection and incorrectly rejecting a signal.

To determine the values of the parameters that characterize the detected signal, we saw how to construct the probability distribution that describes how likely different parameterizations $\mu$ are. We identified $\hat{\mu}$ as the mode of the distribution, i.e., the parameterization that maximized the probability density, or the most likely parameterization. Owing to detector noise, $\hat{\mu}$ differs in a random fashion from the unknown $\tilde{\mu}$ that actually describes the signal. We characterized our uncertainty over the actual description of the signal by specifying a volume $V(P)$ in the parameter phase space, centered on $\hat{\mu}$, such that the $\tilde{\mu} \in V(P)$ with probability $P$.

We then proceeded to exploit these techniques to anticipate the precision with which the parameterization of a particular signal can be determined by a given detector: i.e., we evaluated the sensitivity of the detector to the signal from a class of sources.

To do so, we found the probability distribution of $\tilde{\mu} - \hat{\mu}$ and defined volumes $V(P)$ in phase space such that $\tilde{\mu} \in V(P)$ with probability $P$. These volumes determine the precision with which we expect we can determine the signal parameters in a real observation. In the interesting limit of a strong signal the anticipated probability distribution of $\tilde{\mu} - \hat{\mu}$ for fixed $\hat{\mu}$ is close to Gaussian and the associated volumes $V(P)$ are ellipsoids. In this limit we found approximate techniques for determining the size and orientation of this ellipsoid. Both the exact and approximate expressions developed provide a powerful means of studying the sensitivity of a proposed detector or detector configuration to a source of gravitational radiation. These techniques are currently being employed to study the sensitivity of the LIGO detectors to binary coalescence [23], precessing axisymmetric neutron stars [24], and
non-axisymmetric neutron stars [25].

As an example of the process of measurement, we evaluated the variance in the mass and angular momentum of a perturbed black hole as determined by observations in a gravitational wave detector. These results improve upon those found earlier (cf. Echeverria [5]), and we discussed the origin of the differences.

The LIGO detector, currently under construction, and the LAGOS detector, currently being designed, are both very sensitive to gravitational radiation from perturbed black holes. A perturbation of a $50 \leq M_\odot \leq 100 \, M_\odot$ black hole that radiates as little as $10^{-7}$ of the black hole mass should be observable with LIGO at the distance of the Virgo cluster of galaxies, and a perturbation of a $10^6 \leq M_\odot \leq 10^7 \, M_\odot$ black hole that radiates as little as $10^{-8}$ of the black hole mass should be observable by LAGOS throughout the Universe (cf. eqn. 4.8).

ACKNOWLEDGMENTS

I am glad to thank David Chernoff, Fernando Echeverria, Eanna Flannagan, and Kip Thorne for helpful conversations. I also gratefully acknowledge the support of the Alfred P. Sloan Foundation. This work was supported by a grant from the National Aeronautics and Space Administration (NASA grant NAGW-2936).

FIGURES

FIG. 1. The expected signal-to-noise ratio (SNR) of the $l = m = 2$ mode of a perturbed black hole as a function of the angular momentum parameter $a$. The dependence of the SNR on the black hole mass, distance, total energy radiated, and the detector noise PSD has been scaled out, leaving only the dependence on the angular momentum parameter. For more details see equation 4.8 and surrounding text.

FIG. 2. The expected standard deviation of the black hole angular momentum parameter ($\sigma_a$), mass ($\sigma_M/M$), initial moment of perturbation ($\sigma_T/M$), and perturbation amplitude ($\sigma_V/V$) as a function of the angular momentum parameter $a$. The dependence of these standard deviations on the signal-to-noise ratio (SNR) $\rho$ has been scaled out as shown. For more details see equations 4.20a, 4.21a–4.21c and surrounding text.

FIG. 3. The correlation coefficients for errors in the angular momentum parameter $a$, mass $M$, initial moment of perturbation $T$, and perturbation amplitude $V$ as a function of angular momentum parameter. For more details see equations 4.21d–4.21i and surrounding text.

FIG. 4. Like figure 2, except that the total energy radiated by the perturbation is held fixed instead of the SNR. Compare with figures 1 and 2. For more details see §IV.
