Evolution of oxide and nitride inclusions during processing of stainless steel

Y. Kacar¹, D. Kruger², and P.C. Pistorius¹

Synopsis

Because of its superior properties, stainless steel has been widely used for many applications. Nonmetallic inclusions can influence the quality of stainless steel products. A set of samples was used to track the response of inclusion composition during processing of a heat of titanium-bearing 18% chromium steel, from deoxidation after decarburization, to the solidified slab. The oxide inclusions responded as expected to additions of deoxidizers and calcium treatment, changing from silica to alumina and spinels, and then to calcium aluminates. The samples confirmed that titanium nitride can nucleate on liquid calcium aluminates during steel solidification.

Keywords

stainless steel, inclusion, oxides, titanium nitride precipitation, solidification.

Introduction

Nonmetallic inclusions that can be present in stainless steels include oxides, nitrides, and sulphides (Park and Kang, 2017). In this work we studied changes in oxide inclusions and the associated formation of titanium nitride and niobium carbonitride during processing of a ferritic stainless steel (containing 18% Cr). The investigation was based on a previous study that considered the change in oxide inclusions when processing a similar ferritic stainless steel in the same plant (Kruger and Garbers-Craig, 2017).

Background

The stainless steel production route typically includes melting of raw materials in an electric arc furnace (EAF), removing excess carbon by argon-oxygen decarburization (AOD) or vacuum decarburization, establishing the final temperature and composition of the liquid steel by ladle treatment, and continuous casting (Washko and Aggen, 1990). During processing, the steel can pick up nitrogen from the use of nitrogen during decarburization (in production of austenitic grades), from raw materials and exposure to the atmosphere, or nitrogen can be added intentionally. In ferritic stainless steel (based on binary Fe-Cr alloys), titanium is frequently added to bind nitrogen as titanium nitride.

In such steels, titanium nitride (TiN) normally precipitates during solidification. Titanium nitride inclusions are very hard – indeed, titanium nitride coatings extend the life of cutting tools – and such hard inclusions play an important role in microcrack formation in steel (Fairchild, Howden, and Clark, 2000). Inclusion shape is also important (ibid.). Because of its high entropy of melting, titanium nitride typically forms as faceted (cubic) particles with sharp corners during solidification (Fu et al., 2017). The effect of angular inclusions on the mechanical behaviour of the steel can be strong: In bearing steels the deleterious effect of 6 μm TiN inclusions on the fatigue life of steel is equivalent to that of 25 μm globular oxide inclusions (Monnot, Heritier, and Cogne, 1988).

For the steel considered in this work, both titanium nitride and niobium carbonitride are expected to form during solidification: Figure 1 shows the predicted precipitation of these phases. The composition used in this calculation is that of the steel in the tundish (as measured in this work); see the sample labelled ‘Tundish’ in Table I (more detailed sample descriptions are provided in the section ‘Steel samples’). The expected phases were calculated with Thermo-Calc (Andersson et al., 2002) using the

Others: 18% Cr; balance Fe

Table I

Compositions of steel samples studied in this work (mass percentages); sample descriptions are provided in the ‘Steel samples’ section

Table II

Equilibrium partition coefficients between ferrite and liquid of elements in 18% chromium steel (at the start of solidification; liquidus temperature 1501°C; steel of ‘tundish’ composition in Table I). Calculated with Thermo-Calc

| Element | Cr  | Si   | Mn  | Ti  | Nb  | C   | N   | S    |
|---------|-----|------|-----|-----|-----|-----|-----|------|
|         | 1.01| 0.95 | 0.84| 0.34| 0.15| 0.21| 0.27| 0.10 |

Partitioning increases the concentrations of titanium and nitrogen in the last liquid that remains between ferrite dendrites.

If it forms, titanium nitride can in turn act as a nucleant for ferrite solidification in the equiaxed zone of the solidifying metal. Titanium nitride can nucleate ferrite despite the large lattice disregistry (17%) between the (111) plane of TiN and the (110) plane of ferrite: a Kurdjumov-Sachs orientation relationship between TiN and surrounding ferrite grains was found in 17% chromium steel after solidification (Fu et al., 2017). The ability of TiN to nucleate ferrite is in line with the observation that the as-solidified ferrite grain size is smaller in steels with higher titanium concentrations (Park, 2011).

However, some studies showed that inclusions other than spinel can also nucleate titanium nitride. Observed nuclei included alumina (Wang et al., 2013) and – in steels with negligible Al concentrations – oxides and sulphides containing magnesium (Michelic et al., 2015). The ability of oxides other than spinel to nucleate titanium nitride is potentially of importance in controlling the extent and size of titanium nitride precipitation in finished steel products. To study possible nucleation by non-spinel inclusions, in this work steel samples were examined from various stages of stainless steel processing. Steel refining during these stages caused the composition of the oxide inclusions to change, from silicates (after decarburization...
and deoxidation with ferrosilicon) to spinel (after deoxidation with aluminium) and finally to calcium aluminates (after calcium treatment). In addition, inclusions were examined to detect possible niobium carbonitride precipitation: titanium nitride can act as a substrate for carbonitride formation upon further solidification (Michelic et al., 2015). Titanium nitride and niobium carbonitride are not expected to form while the steel is fully liquid (Figure 1), and so would not affect castability of the steel (that is, the unimpeded flow of steel through caster nozzles, unaffected by solid inclusions). However, formation of these hard phases during solidification can affect the quality of the cast product, so the distribution of these phases – and how these are affected by possible nucleation on oxides – is of great interest.

The primary aim of the work presented here was to test whether oxide inclusions with different compositions can nucleate titanium nitride during solidification. In particular, we investigated whether titanium nitride can form on liquid calcium aluminates (present after calcium treatment), in addition to the previously documented nucleation of titanium nitride by spinels (which was expected to occur in samples taken before calcium treatment).

**Titanium nitride stability**

Figure 1 shows that titanium nitride is expected to form during solidification. To illustrate why this phase would not form in the liquid steel at temperatures above the melting point, Figure 2 gives the calculated solubility of TiN in the steel at two temperatures: 1505°C (just above the liquidus temperature) and 1550°C. The steel composition was taken to be that of the tundish (which was expected to occur in samples taken before calcium treatment).

The minimum size of oxide and nitride inclusions was calculated with Thermo-Calc (Andersson et al., 2002). For steel compositions above the solubility curve, TiN can form in the steel as solid solution.

\[
[Ti] + [N] \rightarrow \text{< TiN >}
\]

In this reaction, the species in square brackets are dissolved in the steel, and the angle brackets indicate the solid phase.

Figure 2 illustrates that the actual steel composition lies below the solubility curve at both 1550°C and 1505°C. Since the latter temperature is just above the liquidus temperature, these curves emphasise the prediction of Figure 1, that TiN is expected to form below the liquidus temperature after some solidification has occurred.

**Experimental work**

**Steel samples**

The process route involved melting in an electric arc furnace (EAF), decarburization followed by deoxidation in an AOD vessel, ladle treatment, and continuous casting. During the plant trial, lollipop samples of liquid steel were taken after different process steps to investigate inclusion evolution. The samples from the AOD vessel to tundish were taken from the same heat, whereas the slab sample was from a different (but similar) heat. The sequence of events is illustrated in Figure 3. As shown in Figure 3, three samples (L1, L2, and L3) were taken at different stages of ladle processing: L1 was taken after deoxidation (with Al) and addition of niobium, L2 was taken after addition of titanium, and L3 after calcium treatment. The sample labelled ‘T’ was taken from the tundish during subsequent continuous casting, and the slab sample was taken after solidification.

**Sample analysis**

Samples were polished metallographically and inclusions were analysed by automated scanning electron microscopy. Imaging and energy-dispersive X-ray (EDX) analysis were performed at an accelerating voltage of 10 kV. The instrument used a silicon drift detector with a thin window (Moxtek AP3.3). Inclusions were detected using backscattered electron imaging. Brightness levels in the backscattered electron images were standardized by setting the brightness of aluminium tape to 70 (on the dimensionless brightness scale of 0–255 used by the instrument) and that of steel to 170 (Tang, Ferreira, and Pistorius, 2017).

After decarburization in the AOD vessel, ferrosilicon was added for deoxidation and recovery of chromium from slag. The resulting silica-rich slag was skimmed off the steel before ladle treatment to prevent reoxidation and to increase alloy yield. Slag formers and aluminium lump (for deoxidation) were added subsequently. Ferroniobium was added after aluminium deoxidation; the first ladle sample was taken after this addition. Low-Al titanium scrap (98–99% Ti) was then added, and another sample taken. Some 3–4 minutes after titanium addition, calcium silicide was added for inclusion modification, and another sample taken. Five minutes of soft stirring was applied after injection of calcium silicide.

**Figure 2—Calculated TiN solubility – at two temperatures – in steel with a similar composition to that studied in this work, but with variable Ti and N concentrations. The actual steel composition in the tundish is indicated by the cross**

**Figure 3—Sequence of events during steel production, showing additions and taking of samples. Sample descriptions are provided in the ‘Steel samples’ section**

After decarburization in the AOD vessel, ferrosilicon was added for deoxidation and recovery of chromium from slag. The resulting silica-rich slag was skimmed off the steel before ladle treatment to prevent reoxidation and to increase alloy yield. Slag formers and aluminium lump (for deoxidation) were added subsequently. Ferroniobium was added after aluminium deoxidation; the first ladle sample was taken after this addition. Low-Al titanium scrap (98–99% Ti) was then added, and another sample taken. Some 3–4 minutes after titanium addition, calcium silicide was added for inclusion modification, and another sample taken. Five minutes of soft stirring was applied after injection of calcium silicide.
Evolution of oxide and nitride inclusions during processing of stainless steel

As shown later, niobium carbonitride inclusions were brighter than the steel matrix, and were evaluated by manual analysis.

Results: Inclusion changes during processing

Inclusion compositions and typical inclusion images are given in Figure 5, with average inclusion sizes (apparent size, from polished sections) and number of inclusions detected per unit area shown in Figure 6. In Figure 5, inclusion compositions are plotted as mole fractions. To show the distribution of compositions, the size of each triangular symbol is scaled proportionately to the area fraction of inclusions with a particular composition – larger triangles indicate that inclusions of that composition were more common. Although multiple elements were analysed in the inclusions in each sample, in general the inclusions contained a small set of major elements. Because quantitative analysis of oxygen and nitrogen is not reliable for micrometre-sized inclusions, the compositions are shown in terms of the metallic elements. For example, inclusions in the sample taken after deoxidation with aluminium (Figure 5b) contained mostly MgO and Al$_2$O$_3$, with CaO in a few cases; these are shown as Mg, Al, and Ca in the ternary composition plot.

Manual SEM analysis was used to confirm identification of specific inclusion types that were detected by automated inclusion analysis. For example, inclusions in the sample taken after titanium addition (Figure 5c) contained titanium nitride – which was identified from its brightness in the backscattered electron image (brighter than oxides containing Mg and Al; darker than the steel matrix), the presence of titanium, and the absence of oxygen. Similarly, niobium carbonitride (which is expected to form during the last stages of solidification of the samples; see Figure 1) was identified from its brightness (brighter than the steel matrix), presence of niobium and carbon (at higher than background levels), and absence of oxygen.

In the AOD process, oxygen diluted with argon is blown into the metal bath to decarburize the crude stainless steel. Some chromium is oxidized in the process and is taken up by the slag; ferrosilicon is added for deoxidation and chromium recovery from slag at the end of the AOD process. The resulting inclusions were mainly SiO$_2$, containing some traces of manganese (Figure 5a). During subsequent ladle treatment, addition of aluminium converted the inclusions to alumina and spinel (Figure 5b). The conversion from silica to alumina occurred because aluminium has a higher affinity for oxygen than does silicon (Turkdogan, 1983). The added aluminium also deoxidized the steel more deeply, forming new oxide inclusions from the previously
Evolution of oxide and nitride inclusions during processing of stainless steel

Figure 6—Changes in the average size of inclusions in samples from different stages of steel processing (upper graph), together with the number of inclusions detected (lower graph). Sample numbering corresponds to the sequence shown in Figure 3.

Dissolved oxygen. Although it is possible to produce stainless steels that are deoxidized with silicon only, deeper deoxidation by aluminium has several advantages:

- Ferrosilicon frequently contains some aluminium; even small aluminium concentrations can change the deoxidation product from silica to alumina and spinel (Todoroki et al., 2001). Uncontrolled formation of alumina and spinel would cause clogging of caster nozzles if these oxides were left untreated. Intentional aluminium additions help to eliminate the variability in the deoxidation product caused by varying aluminium concentrations in ferrosilicon.
- If this steel grade were deoxidized with only silicon, addition of titanium would result in the formation of TiO₂ or Ti₃O₅; that is, the steel would be titanium-deoxidized.

To test whether titanium oxide would form in this steel in the absence of dissolved aluminium, the equilibrium phases in steel with a composition shown in Table I were calculated, but without aluminium and with a total oxygen content of 30 ppm (by mass), for a temperature of 1550°C. The calculation was performed with FactSage 7.3 using the FSstel and FToxid databases (Bale et al., 2016). The equilibrium oxide was predicted to be Ti₃O₅, with 17 ppm oxygen remaining in solution. If titanium additions were made to steel that was not deoxidised with aluminium, formation of titanium oxide would lower the titanium yield. Another side effect is that some of the resulting titanium oxide inclusions would float out in the mould during continuous casting.

Titanium oxide pick-up by the mould can lead to formation of solid perovskite in the mould flux, affecting lubrication in the continuous caster mould (Mukongo, Pistorius, and Garbers-Craig, 2004).

Dissolved aluminium that remained in the steel after deoxidation further reacted with MgO in slag or refractory, transferring dissolved magnesium into the steel. The dissolved magnesium reacted with alumina inclusions to convert these to Al₂O₃-MgO inclusions (Kumar and Pistorius, 2018). MgO is only slightly soluble in Al₂O₃ (the atomic ratio of Mg to Al in Al₂O₃ at saturation is 1.1×10⁻⁴ at 1530°C) (Roy and Coble, 1968). Because of the near-zero solubility of MgO in Al₂O₃, any MgO pick-up caused the formation of spinel, a solid solution based on Mg₂Al₂O₄. In addition to deoxidation with aluminium, the steel was alloyed with niobium before the first ladle sample was taken. Figure 5b shows that some niobium carbonitride was detected in the immediate vicinity of the alumina-spinel inclusions. Based on solidification calculations (similar to those reported in Figure 1), the niobium carbonitride precipitated during solidification of the steel sample.

Titanium alloying did not change the oxide inclusions—their size remained a mixture of alumina and spinel (Figure 5c). However, titanium nitride precipitation was evident after titanium addition to the liquid steel. Figure 5c shows an example of titanium nitride precipitated on a spinel inclusion, surrounded by niobium carbonitride. This spatial relationship reflects the precipitation sequence shown by Figure 1—during solidification, titanium nitride nucleated first (on the existing alumina and spinel inclusions), followed by niobium carbonitride formation during the last stages of solidification. The Mg-Al-Ti ternary plot in Figure 5c illustrates a continuous range of inclusion compositions, ranging from oxides (alumina and spinel) to TiN. This distribution reflects the random intersection of the sample polishing plane with inclusions containing both oxide and TiN.

Subsequent calcium treatment successfully converted the alumina and spinel inclusions to calcium aluminates containing some MgO (Figure 5d). Figure 6 shows that the size of the inclusions (oxides surrounded by titanium nitride) decreased after calcium treatment, with a corresponding increase in the number of inclusions. This has also been observed upon calcium treatment of aluminium-killed (non-stainless) steels; the decrease is caused by formation of nuclei of calcium oxide and calcium sulphide, from which the calcium aluminates grow (Ferreira, 2018). Oxide inclusion compositions that lie within the thin grey boundary in the Mg-Ca-Al diagrams would be more than 50% liquid at 1550°C—this boundary was calculated in previous work, using the MgO-CaO-Al₂O₃ phase diagram (Verma et al., 2012). This is the case for the last ladle sample (as well as the tundish and slab samples), demonstrating the success of calcium treatment in converting the solid alumina and spinel inclusions to liquid calcium aluminates.

The inclusions in subsequent samples (tundish and slab, Figure 5e and 5f) are similar in composition. The inclusions consist of calcium aluminates surrounded by titanium nitride and niobium carbide. However, the inclusions in the tundish sample are somewhat larger than those in the last ladle sample, reflecting coarsening of the calcium aluminates by collision and agglomeration (Ferreira, 2018) and also some additional nitrogen pick-up (Table I). The nitrides in the slab are much larger (Figure 5f; note the difference in magnification), reflecting the much longer slab solidification time compared with the lollipop samples taken from the liquid steel.

Discussion

This set of samples confirmed that titanium nitride can nucleate on different oxide inclusions, and not just on spinels. Titanium nitride was found around spinel, alumina, and liquid calcium aluminates. Based on these results, the sizes of titanium nitride inclusions in solidified steel would depend on the number density of oxide inclusions (if fewer oxides are present, fewer titanium nitrides would form and grow larger).
Evolution of oxide and nitride inclusions during processing of stainless steel

the nitrogen concentration in the steel, and solidification rate. The combination of nitrogen pick-up during steel processing (Table I), reduction in the number density of oxides, and slower solidification cause the nitrides in the slab to be much coarser than in any of the samples taken from liquid steel. Macrosegregation would also affect the size and concentration of inclusions. Preliminary investigations indicated that the nitride inclusions in samples taken from near the slab surface were smaller than those from the centre of the slab, indicating a possible macrosegregation effect.

Since the titanium nitrides and niobium carbonitrides formed during solidification, these would not have affected the castability of the liquid steel. Steel castability depends on the concentration and physical state of inclusions that are present in the liquid steel. From these analyses, the liquid steel contained liquid calcium aluminates (after calcium treatment), which would have ensured good castability.

Conclusions

The additions of deoxidizers and calcium during processing of an 18% Cr ferritic stainless steel resulted in the expected change in the composition of the oxide inclusions – from silica after deoxidation with ferrosilicon to alumina and spinel after deoxidation with aluminium, and finally to calcium aluminates upon calcium treatment. However, the major phase in the inclusions in the solidified samples was titanium nitride, not oxides. Titanium nitride was found to precipitate on calcium aluminates, and not just on spinels (with subsequent growth of niobium carbide/nitride on the titanium nitride). The observed inclusion morphology is consistent with the expected changes during solidification (based on Thermo-Calc predictions); only oxide inclusions were present in the liquid steel; titanium nitride formed during solidification, followed by niobium carbide during the last stages of solidification.

Nucleation of titanium nitride on oxide inclusions implies that the number density and spatial distribution of nitrides would be dictated by the number and spatial distribution of oxides during steel solidification; the volume fraction of nitrides depends on nitrogen concentration. The net result is that, in the heat studied in this work, relatively coarse nitrides were present in the slab sample.
