Shangri-La is a wine region that has the highest altitude vineyards in China. This is the first study investigated the biodiversity of non-\textit{Saccharomyces} yeasts associated with spontaneous fermentation of Cabernet Sauvignon wines produced from two sub-regions (Lancang River and Jinsha River) of Shangri-La. The culturable yeasts were preliminarily classified based on their colonial morphology on the Wallerstein Laboratory nutrient agar plates. Yeast species were identified by the sequencing of the 26S rRNA D1/D2 region and the 5.8S rRNA ITS region. Twenty-five non-\textit{Saccharomyces} yeast species belonging to sixteen genera were isolated and identified in Shangri-La wine region. \textit{Candida}, \textit{Hanseniaspora}, \textit{Pichia}, and \textit{Starmerella} were found in both sub-regions, but the Lancang River showed more diverse yeast species than the Jinsha River. Shangri-La not only exhibited high diversity of non-\textit{Saccharomyces} yeasts, and furthermore, seven species of non-\textit{Saccharomyces} yeasts were exclusively found in this region, including \textit{B. bruxellensis}, \textit{D. hansenii}, \textit{M. guilliermondii}, \textit{S. vini}, \textit{S. diversa}, \textit{T. delbrueckii} and \textit{W. anomalus}, which might play an important role in distinctive regional wine characteristics. This study provide a relatively comprehensive analysis of indigenous non-\textit{Saccharomyces} yeasts associated with Cabernet Sauvignon from Shangri-La, and has significance for exploring 'microbial terroir' of wine regions in China.

Wine fermentation is a complex biochemical process conducted by many different microorganisms, and yeasts play a major role in this process\textsuperscript{1}. Although wine could be produced spontaneously by wild yeasts on the surface of grapes\textsuperscript{2}, inoculation of commercial \textit{Saccharomyces cerevisiae} yeast is the most common operation in current wine production in order to avoid several potential problems (e.g. sluggish fermentation) and to achieve final products with uniform quality\textsuperscript{3}. According to some opinions, the resulting wine, however, is more like 'industrial' products and loses its 'natural' property such as diversity and distinctive characteristics\textsuperscript{2}.

To produce wine with distinctive characteristics, researchers and enologists tried to inoculate non-\textit{Saccharomyces} yeasts during alcoholic fermentation\textsuperscript{4-7}. In these studies, non-\textit{Saccharomyces} yeasts were either co-inoculated or sequentially inoculated with \textit{S. cerevisiae} yeast, and the resultant wines generally exhibited more varietal characteristics and distinctive sensory attributes. In addition, non-\textit{Saccharomyces} yeasts have also been used in the production of other beverages, such as beer\textsuperscript{8} and spirit\textsuperscript{9,10}. Although a few non-\textit{Saccharomyces} yeasts are commercially available, there is an increasing interest in exploring non-\textit{Saccharomyces} yeasts worldwide and their potential usage in wine production.

Some research have demonstrated that indigenous yeasts are an important part of the 'terroir' in different wine producing regions around the world\textsuperscript{11-14}. The density and diversity of those indigenous yeasts on grape are closely related to numerous factors, such as the variety and maturity of grape, geographical location and climatic conditions of vineyard, and the practices of viticulture\textsuperscript{11}. China has a fast-growing wine industry which includes

Results

Oenological parameters in grape juice and spontaneously fermented wine. The oenological parameters in Cabernet Sauvignon grape juice and spontaneously fermented wines from Shangri-La were shown in Table 1. Grapes from each vineyard exhibited various ripeness with the reducing sugar concentration ranging from 186.74 to 265.95 g/L, total acidity ranging from 3.42 to 8.55 g/L, and the pH ranging from 3.26 to 3.97. After spontaneous fermentation, most of wines were fermented to dryness with residual sugar concentration less than 5.00 g/L, except for wines made from L-XD (10.91 g/L) and J-BZL (14.14 g/L). Due to the variations in ripeness of grapes and the residual sugar in wines, the alcohol content of resultant wines ranged between 10.79 and 15.46%. There was an increase in the total acidity during the spontaneous fermentation. The concentration of volatile acidity varied significantly among the wines ranging from 0.60 to 1.92 g/L. The pH of final sample wines varied from 3.38 to 3.84.

Yeast isolation and identification. The detailed information of 26S rRNA D1/D2 region and 5.8S rRNA ITS region of representative isolates were listed in Table S1. Most yeast isolates were identified at high similarity (> 99.00%) of D1/D2 and ITS sequences with the corresponding type strains. The reliable identification results were also confirmed by phylogenetic analysis (Figs. 1, 2). Although a high similarity was shown in BLAST results of 26S rRNA D1/D2 region, certain differences were observed in 5.8S rRNA ITS region among several isolates and related type strains, including L-SN-25, L-AD-7, L-AD-17, L-XD-23 and L-NT-69 (Table S1). As no type strain is available for Metschnikowia fructicola, the identification of L-AD-7 was based on BLAST analysis of 26S rRNA D1/D2 region of GXZJD32 (KC160603.1) and 5.8S rRNA ITS region of AP47 (FJ919773.1) (Table S1).

Biodiversity of non-Saccharomyces yeasts in Shangri-La region. A total of 2168 yeast isolates were collected during spontaneous fermentation of Cabernet Sauvignon wines from seven samples within the Lancang and Jinsha River Basins of Shangri-La wine region. As shown in Table 2, twenty-five different non-Saccharomyces yeast species belonging to sixteen genera were identified by colonial morphology and molecular methods. The identified yeast species include Aureobasidium pullulans, Brettanomyces bruxellensis, Candida glabrata, Candida oleophila, Debaryomyces hansenii, Hanseniaspora opuntiae, Hanseniaspora uvarum, Hanseniaspora vineae, Metschnikowia fructicola, Metschnikowia pulcherrima, Meyerozyma guilliermondii, Pseudotrichosporon roseum, Pichia kudriavzevii, Pichia thermodenatis, Pichia tericola, Rhodotorula glutinis, Saccharomyces cerevisiae, Saccharomyces bayilis. There were more non-Saccharomyces yeast species isolated from the Lancang River than the Jinsha...
Figure 1. Phylogenetic tree of representative non-Saccharomyces yeast isolates obtained from Shangri-La wine region based on the sequence analysis of the 26S rRNA D1/D2 region using the maximum-likelihood method. The scale bar shows 0.05, Bootstrap support values were estimated based on 1000 replicates and are shown above the branches (> 50%).
Figure 2. Phylogenetic tree of representative non-\textit{Saccharomyces} yeast isolates obtained from Shangri-La wine region based on the sequence analysis of the 5.8S rRNA ITS region using the maximum-likelihood method. The scale bar shows 0.05, Bootstrap support values were estimated based on 1000 replicates and are shown above the branches (>50%).
Within the sixteen non-\textit{Saccharomyces} yeast genera identified in Shangri-La region, \textit{Saccharomyces} was the most abundant species. Interestingly, \textit{Pichia} yeasts are exclusively found in Shangri-La, including \textit{B. bruxellensis}, \textit{D. hansenii}, \textit{M. guilliermondii} and \textit{W. anomalus}.

### Table 2. Frequency of non-\textit{Saccharomyces} yeast isolates from Cabernet Sauvignon spontaneous fermentation of Shangri-La wine region. ‘−’ means yeast species was not detected in present work.

| Yeast species | L-NT | L-XD | L-LIT | L-SN | L-AD | J-BZL | J-DR | Representative isolates |

Discussion

Compared to most wine regions of China\textsuperscript{19}, the Cabernet Sauvignon harvested from Shangri-La exhibited greater maturity degree, which was related to the ideal viticulture environment of this region\textsuperscript{16}. In most spontaneously fermented wines, the concentration of volatile acidity were much higher than acceptable level (0.7 g/L)\textsuperscript{25}. Indeed, most non-\textit{Saccharomyces} yeasts\textsuperscript{23–26} and some wild \textit{S. cerevisiae} yeasts\textsuperscript{25} may produce excess volatile acidity during spontaneous fermentation. While a marked increase of total acidity in final wines suggested that some yeast species being found in present study could be used for improving the wine contained insufficient acidity\textsuperscript{27}.

Within the sixteen non-\textit{Saccharomyces} yeast genera identified in Shangri-La region, \textit{Hanseniaspora} and \textit{Starmerella} were the most frequent isolates. The predominant species of these two genera were \textit{H. uvarum} and \textit{S. basilaris (C. zemplinina)}, which is in agreement with the findings of previous research\textsuperscript{15,12,18,28}. These two species were commonly found in grape and wine, thus more attention has been paid in vinification research and application\textsuperscript{19}. In addition, four members of \textit{Hanseniaspora} and \textit{Starmerella} also existed in Shangri-La region, namely \textit{H. opuntiae}, \textit{H. vineae}, \textit{S. apicola (C. apicola)} and \textit{S. stellata (C. stellata)}.

The \textit{Pichia} is another abundant genus associated with spontaneous fermentation of Cabernet Sauvignon in Shangri-La region. Among the four \textit{Pichia} species isolated, \textit{P. occidentalis} was the most abundant species. Interestingly, \textit{P. occidentalis} had also been found in Roussanne that grown in Beijing\textsuperscript{17}. While for other wine regions of China, the widely distributed species of this genus was \textit{Pichia fermentans}\textsuperscript{16,21}. Several studies indicated that some \textit{Pichia} species, such as \textit{P. klyveri}, \textit{P. kuhiavzevii (I. orientalis)}, \textit{P. terricola (I. terricola)} and \textit{Pichia fermentans} have the potential to enhance wine aroma by releasing glycosidically bound aroma precursors from grape must\textsuperscript{23} or
producing volatile compounds during fermentation. But there is little information about *P. occidentalis* (*I. occidentalis*) in wine production, which might be worth further study.

Two *Metschnikowia* species, including *M. fructicola* and *M. pulcherrima*, have been isolated in the samples of L-AD and L-SN, respectively. *M. pulcherrima* was the common species that had been found on Cabernet Sauvignon among most wine regions of China. Although *M. fructicola* had previously only been isolated on Roussanne in Beijing, the present study indicated that it may also associated with Cabernet Sauvignon that grown in China. According to studies conducted by Floriana Boscaino, Elena González-Royo and C. Varela, the usage of *M. fructicola* or *M. pulcherrima* during fermentation could improve the aromatic profile of resultant wine.

In this study, *P. flavescens* (*C. flavescens*) was only accounted for a small proportion in the sample of L-LTJ. Although a previous study reported that *P. flavescens* (*C. flavescens*) was found as a common yeast species isolated from Cabernet Sauvignon, Merlot and Chardonnay in Shacheng, Changli, Wuwei and Penglai of China, this species seems unlikely associate with grape due to the low frequency observed in this study, which was in agreement with the view of Brysch-Herberg.

*A. pullulans* (so called black-yeast) and *R. glutinis*, which have the capacity of pigment metabolism, were found in present work. *A. pullulans* is one of the most well-adapted saprophytes on grape berries, however the distribution of *A. pullulans* was not very widespread in Shangri-La as well as other regions of China. It was only detected in sample of L-SN and exhibited a low isolation frequency. It has been reported that various enzymes (*e.g.* pectinase, cellulases and β-glucosidase) produced by *A. pullulans* could be beneficial to the flavor of wine. Additionally, due to antifungal and antibacterial activity, this species might be used to against some biological diseases of vine. Although *R. glutinis* were accidentally isolated in two samples of Shangri-La, *Rhodotorula* sp. are generally considered as typical phyllophoric yeasts and thus rarely associated with yeast community of grape berries in China. Although some *Rhodotorula* sp. can produce β-glucosidase and α- and β-fructofuranosidase to release bound aroma precursors, these enzymes are usually not used in wine production.

*Zygosaccharomyces bailii* was found in the sample of L-NT. It is one of the most dangerous wine spoilage species, which are known to produce off-flavors and form cloudiness even under high alcohol condition. Although *Z. bailii* exhibited low isolation frequency in Shangri-La, some precautions should be taken in wine production.

There were seven non-*Saccharomyces* yeast species which showed regional characteristics were exclusively found in Shangri-La wine region, including *B. bruxellensis*, *D. hansenii*, *M. guilliermondii*, *T. delbrueckii*, *W. anomalus*, *S. vini* and *S. diversa*. To the best of our knowledge, this is the first time that these non-*Saccharomyces* yeast species have been isolated from wine regions of China. *T. delbrueckii* is one of the commercialized non-*Saccharomyces* yeast for wine production. Several positive influences of *T. delbrueckii*, such as enhancing the fruity aroma style, increasing glycerol concentration, reducing volatile acidity and improving foam properties, have been confirmed in the production of grape wine. *W. anomalus* and *D. hansenii* have also been tested in wine-related research and shown positive effects on wine aroma quality. Although *M. guilliermondii*, *S. vini* and *S. diversa* have been found in wine, beer and some fruits, little study has been conducted for fermentation characteristics of these yeasts in wine or other alcoholic beverages.

Compared with other wine regions of China that have been reported, Shangri-La wine region exhibited greater overall diversity of non-*Saccharomyces* yeast species. Within Shangri-La region, J-BZL showed more non-*Saccharomyces* yeast diversity than other vineyards, which is most probably related to its distinctive grape-growing environment. Compared to other six vineyards in Shangri-La region, the vineyard of J-BZL is very close to the bank of Jinsha River, which provides a high humidity environment ideal for epiphytic microorganism growth on grapes. For L-LTJ and L-SN which located at the foot of Meili Snow Mountain, a rapid decline in temperature during natural period (October) could be one of the possibilities that reduce the diversity of non-*Saccharomyces* yeasts present on their grapes. According to França’s research, soil samples that came from low temperature area exhibited less density of yeast population. Furthermore, low temperature may also make a few yeast become the dominant culturable species and reduce the chance that other species will be isolated. These results confirmed that the geographic locations and climate conditions have great impact on yeast communities and provided more evidence that indigenous yeasts should be considered as an important part of terroir.

**Methods**

**Grape samples and spontaneous fermentation.** Cabernet Sauvignon (*Vitis vinifera* L.) grape samples were collected from seven vineyards (Shangri-La Winery Co., Ltd. Yunnan) located at different altitudes within two sub-regions (Lancang River and Jinsha River) of Shangri-La wine region in Yunan province. Grape samples were harvested by hand with sterile gloves in September and October in 2017. After harvest, grape samples (10 kg) from each vineyard were stored in sterile bags at 4 °C and transported to the laboratory in Kunming within 24 h. The geographical information and the location of sampling vineyards was summarized and shown in Table 3 and Fig. 3, respectively.

Grape samples of each vineyard were destemmed and crushed by hand with sterile gloves, and the must was fermented in two sterilized 5 L glass bottles at 28 °C for 12–18 days. During the fermentation, cap management was carried out once a day until the end of fermentation. Oenological parameters in Cabernet Sauvignon grape juice (reducing sugar concentration, total acidity, and pH) and spontaneously fermented wines (residual sugar concentration, total acidity, volatile acidity, pH and alcohol content) were measured according to the National Standard of the People’s Republic of China: GB/T 15.038–2006, “Analytical Methods of Wine and Fruit Wine”. The concentration of reducing/residual sugar was determined by 3,5-dinitrosalicylic acid method. The content...
of alcohol was determined by density method. The concentration of total acidity was determined by potentio-
metric titration using standard sodium hydroxide. The separation of volatile acidity from wine was carried out
by steam distillation. The concentration of volatile acidity was titrated by standard sodium hydroxide. The value
of pH was determined by pH meter.

Isolation of non-Saccharomyces yeasts. For the isolation of non-Saccharomyces yeasts, fermenting
samples (10 ml) were collected every 3 days from each fermentation bottle. Due to the variation in the fermen-
tation duration, there were 4 fermenting samples collected from L-LTJ, L-SN; 5 fermenting samples collected
from L-NT, L-XD and J-DR; 6 fermenting samples collected from L-AD and J-BZL. The fermenting samples
were diluted into 1:10³ to 1:10⁵ ratios with sterile physiological solution (0.85%, NaCl), plated on the Wallerstein
Laboratory (WL) nutrient agar (Qingdao Hope Bio-Technology Co., Ltd.) and incubated at 28 °C for 5 days
until colonies showed morphological differences. About 10 to 15 colonies showing different colonial morphol-
gy were selected from each WL nutrient agar plate, and then re-streaked on the YEPD agar plate (yeast extract
10 g/L, tryptone 20 g/L, glucose 20 g/L, agar 20 g/L, and chloramphenicol 100 mg/L) for purification. There were
2168 pure yeast cultures in total isolated and stored at 4 °C for further analysis. Glycerol (15% v/v) was added
into yeast culture for long-term storage at -80 °C.

Non-Saccharomyces yeasts identification. Yeast isolates were preliminarily classified according to the
morphology (color, shape, consistency, and size) of their colonies on the WL nutrient agar plate, and a total of
204 isolates were chosen for molecular identification.

Genomic DNA was extracted from three colonies of each isolates by using Rapid Yeast Genomic DNA Iso-
lation Kit (Shanghai Sangon Biotech Co., Ltd.) following the manufacturer’s instructions. The genomic DNA
extracted was identified by analysis of the sequence similarity of the 26S rRNA D1/D2 region and 5.8S rRNA
ITS region. The primers for amplification of 26S rRNA D1/D2 region were NL1 (5′-GCA TAT CAA TAA GCG
GAG GAA AAG -3′) and NL4 (5′-GGT CCG TGT TTC AAG ACG G-3′), and for amplification of 5.8S rRNA ITS
region were ITS1 (5′-TCCGTAAGTGAAACCTGCGG-3′) and ITS4 (5′-TCCTGCTTATTGATATGC-3′).

Table 3. The geographical information of sampling vineyards from Shangri-La wine region. *In sample ID, L-
and J-indicates sample collected from Lancang River and Jinsha River in Shangri-La wine region, respectively.

| Sub-region | Sample ID* | Altitude (m) | Latitude | Longitude | Sample date |
|------------|------------|--------------|----------|-----------|-------------|
| Lancang River | L-NT | 1942 | 28°08′10″ | 98°53′18″ | 2017.09.08 |
|            | L-XD | 2081 | 28°26′55″ | 98°49′35″ | 2017.09.08 |
|            | L-LTJ | 2121 | 28°33′20″ | 98°47′13″ | 2017.10.14 |
|            | L-SN | 2266 | 28°29′38″ | 98°48′7″ | 2017.10.14 |

Figure 3. The location of sampling vineyards from Shangri-La wine region.
All the sample DNAs were amplified in PCRs at a 40 μl reaction volume, containing 2 μl of extracted DNA, 2 μl of each primer (100 μmol/L), 20 μl of Master Mix (ABM) and 14 μl of sterile double distilled H2O. PCR amplification was carried out in an Applied Biosystems, Veriti 96-well Thermocycler, and the PCR thermal cycling conditions were as follows: 5 min at 95 °C; 36 cycles of 1 min at 94 °C, 1 min at 55 °C, 1 min at 72 °C; and finally 10 min at 72 °C.

The PCR products were purified and sequenced by Biomed gene technology Co., Ltd (Beijing). The sequencing results were submitted and compared with those of corresponding type strain (listed in Supplementary Table S1) in the Blast service of the National Center for Biotecnology Information (NCBI http://www.ncbi.nlm.nih.gov/blast).

Phylogenetic analysis was performed to verify the identification of representative isolates. The phylogenetic tree was developed using the Maximum Likelihood methods and the Kimura 2-parameter model by MEGA 7.0: Molecular Evolutionary Genetics Analysis version 7.0 for bigger datasets (Kumar, Stecher, and Tamura 2015). Bootstrap values were calculated from 1000 iterations.

**Statistical analysis.**

All the analyses were performed in triplicate. One-way analysis of variance (ANOVA) was used to analyze the difference of grape and wine samples performed through SPSS 19.0 (IBM Corp., Armonk, New York, U.S.A.) employing Duncan multiple range tests at a significance level of p < 0.05. The results were expressed as the mean value ± the standard deviation.

Acknowledgements
This study was supported by the Free Exploration Project for Academicians of Yunnan Science and Technology Department (2018HA009). The authors thank Dr. Tian from Lincoln University (New Zealand) for the English proof-reading of this manuscript. The authors also appreciate Shanghri-La Winery (Yunnan) Co., Ltd. for providing the grape samples and assistance.

Author contributions
Y.F.Z., S.S.Z. and F.D. designed research and project outline. Y.Z., Q.Y.S., R.Z.M. and L.J.L. performed the sample collection. Y.Z. and Q.Y.S. performed the isolation, identification and data analysis. Y.Z. drafted the manuscript. Y.F.Z. and B.T. revised the manuscript. All authors have read and approved the final version of the manuscript.
