ABSTRACT

We present ice- and gas-phase observations of CO, \(^{13}\)CO and of \(\text{H}_2\text{O}\) in the mid- and far-infrared taken with the Infrared Space Observatory (ISO) short- and long-wavelength spectrometers toward two positions in the Galactic center region (Sagittarius A* and GCS 3). These data are complemented with Caltech Submillimeter Observatory (CSO) observations of the \(J = 3–2\) and \(J = 7–6\) lines of CO. The ISO and CSO data indicate that the absorbing gas is extremely cold, \(T_c \approx 10\) K, suggesting that it is located in the dark clouds of the different spiral arms that intersect the lines of sight. From the analysis of the CO absorption, we derive \(^{13}\)CO gas-phase column densities of \(1.1 \times 10^{17} \text{cm}^{-2}\) toward Sgr A* and GCS 3, respectively. The \(\text{H}_2\text{O}\) gas column density in the direction of Sgr A* is \(\approx 2 \times 10^{16} \text{cm}^{-2}\). The derived CO/\(\text{H}_2\text{O}\) and gas/solid abundance ratios corresponding to these cold clouds are remarkably similar along the two lines of sight. We find that nearly all the CO is in the gas phase, while the \(\text{H}_2\text{O}\) is almost entirely frozen onto dust grains. Finally, the \(N_{\text{gas+ice}}(\text{CO})/N_{\text{gas+ice}}(\text{H}_2\text{O})\) abundance ratio is \(\approx 5\), implying that \(\text{H}_2\text{O}\) formation processes are highly efficient.

1. INTRODUCTION

The water molecule plays an important role in the chemistry of interstellar and circumstellar clouds, but due to its high abundance in the Earth’s atmosphere, only some weak rotational lines (Cernicharo et al. 1990, 1994) are observable from the ground. It was only with the advent of the Infrared Space Observatory (ISO; Kessler et al. 1996) that extensive observations of the far-infrared thermal lines of water vapor could be used to obtain reliable estimates of the water vapor abundance in molecular clouds. Mapping of the Sagittarius B2 molecular cloud (Cernicharo et al. 1997b) has definitely shown that \(\text{H}_2\text{O}\) is a ubiquitous molecule in the cores of warm molecular clouds with an abundance of \(\approx 10^{-5}\). In addition, maps of the emission of several \(\text{H}_2\text{O}\) lines in Orion IRc2 have been obtained by Cernicharo et al. (1997a, 1999) showing that the abundance of \(\text{H}_2\text{O}\) is close to \(10^{-7}\) in the shocked gas. \(\text{H}_2\text{O}\) observations of the central position of Orion have also been obtained by van Dishoeck et al. (1998), González-Alfonso et al. (1998), and Harwit et al. (1998). All these new data refer to the warm regions of molecular clouds. While there is also strong evidence for a high water depletion onto the ice mantles of dust grains in the coldest regions, no water vapor has been detected in the direction of dark clouds, probably because of the low temperature and density prevailing in these objects.

In order to study the coldest and least disturbed regions of molecular clouds, we have examined the ISO archive spectra of two positions in the Galactic center, where absorption from the intervening medium is known to occur (Lutz et al. 1996 and references therein). In the case of Sagittarius A*, this cold gas is also seen in the form of sharp and deep absorption features at 0, –30, and –50 km s\(^{-1}\) in various millimeter transitions of \(\text{NH}_3\) and CO against the broad background produced by the warm clouds in Sgr A West (Serabyn & Güsten 1986; Sutton et al. 1990). The ISO data, together with submillimeter observations of the \(J = 3–2\) and \(J = 7–6\) lines of CO, have been modeled to place constraints on the abundances of these molecules in both the gas and the solid phases.

2. OBSERVATIONS

All data were obtained with the ISO short- and long-wavelength spectrometers (SWS; de Graauw 1996; LWS; Clegg et al. 1996) using the full-resolution grating mode of the SWS (\(\lambda/\Delta\lambda = 1500–2000\)) and the grating and Fabry-Pérot (FP) modes of the LWS (\(\lambda/\Delta\lambda = 300\) and 9000, respectively). The effective SWS aperture in the 4–7 \(\mu\)m range is about \(14^\circ \times 20^\circ\), whereas the LWS aperture is circular and \(\approx 70^\circ\) in diameter. In both cases, the apertures include several sources (see Moneti et al. 2001 for GCS 3). The aperture centered on Sgr A* also includes several pointlike and diffuse sources. OLP 7.1 archive data were further processed with the ISAP package.

The results are shown in Figures 1, 2, and 3. In order to resolve the velocity structure of the absorbing/emitting gas in the direction of Sgr A*, we have made observations of the \(J = 3–2\) and \(J = 7–6\) lines of CO in the direction of this source with the Caltech Submillimeter Observatory (CSO). These observations were made in position switching, with the off position 4\(^\circ\) outside the Galactic plane. A region of 10\(^\prime\) \times 6\(^\prime\) was mapped in the \(J = 3–2\) line of CO, and a few positions were observed in the \(J = 7–6\) line of the same species. The system temperatures at the frequencies of the \(J = 3–2\) and \(J = 7–6\) lines of CO were 760 and 6000 K, respectively, and the spectral resolution was 0.5 MHz. The results for the central position of our maps, Sgr A*, are shown in Figure 3.

3. RESULTS AND DISCUSSION

In order to determine the physical conditions of the foreground cold gas from the ISO \(\text{H}_2\text{O}\) and CO data, we have used

\(^1\) Based on observations with the Infrared Space Observatory, an ESA project with instruments funded by ESA member states (especially the PI countries: France, Germany, the Netherlands, and the United Kingdom) and with the participation of ISAS and NASA.

\(^4\) ISAP is a joint development of the LWS and SWS instrument teams and data centers. Contributing institutes are CNRS, IAS, IPAC, MPE, RAL, and SRON.
Fig. 1.—(a–c) ISO SWS spectra of the stretching mode of CO. (d–f) The bending mode of water vapor in the direction of Sgr A* (ISO observation number [ION] 46301102). Panels (a) and (d) show the observations and the continuum (including ices); (b) and (e) show the contribution of the ices and of the warm CO; (c) and (f) show the normalized spectrum and model spectrum (shifted for clarity); and (g) shows the details of the ortho- and para-H$_2$O transitions.

Fig. 2.—CO spectrum and model for GCS 3 (ION 32701543)

Fig. 3.—CO spectrum (ION 46301103) and model (ION 32701543) at velocities of $-5$, $-30$, and $-55$ km s$^{-1}$, have also been seen in many other molecular and atomic species and correspond to cold gas in the line of sight that produces the series of $R$ and $P$ lines up to $J = 7$ in the rovibrational band of CO (see Fig. 1). The CSO maps indicate that the absorption features are present in all positions where the broad emission is seen. Hence, both broad emission and narrow absorption fill the ISO LWS and SWS beams. Consequently, prior to the analysis of the rovibrational absorption, the broad components due to the ices and, in the case of Sgr A*, to the warm CO gas in the Sgr A West region (Sutton et al. 1990), had to be analyzed and removed. In the following discussion, we will assume $^{13}$CO/ (Langer & Penzias 1990).

3.1. Modeling the Warm CO Gas in Sgr A West

The CO rovibrational data (SWS) have been modeled by a single component with $T_{\text{rot}} = 150$ K, $\Delta v = 200$ km s$^{-1}$, and $N$(CO) = $1.0 \times 10^{17}$ cm$^{-2}$. The assumed line width is suggested by our $J = 7$–6 line data and by the LWS-FP observations of some CO lines (not shown here). The LWS grating data toward Sgr A* show CO pure rotational line emission from the $J = 14$–13 up to the $J = 21$–20 transitions (some of them are shown in the inset panel in Fig. 3b). Assuming that the emission fills the beam, and using a large velocity gradient code and the collisional rates of Schinke et al. (1985), the observed intensities are reproduced, within 20%–30%, for $n$(H$_2$) = $3 \times 10^3$ cm$^{-3}$, $T_k = 250$ K, $N$(CO) = $1.2 \times 10^{17}$ cm$^{-2}$ with the assumed line width. The corresponding excitation temperatures vary between 160 and 180 K from the $J = 14$–13 to the $J = 21$–20 rotational lines of CO, i.e., similar to the rotation temperature derived from the SWS rovibrational absorption of CO. Note that the region is rather complex and that the column density we derive rep-
3.2. The CO and H$_2$O Ices

The ices of CO, XCN, and H$_2$O are commonly found in the spectra of young, deeply embedded sources. CO and XCN ice absorption bands were modeled as simple Gaussians; two Gaussians of different widths and central wavelengths were used for the polar and nonpolar CO ices (Chiar et al. 1998). The main goal of this fitting was to remove the CO ice contribution from the continuum; nevertheless, we could derive $N$(CO ice) $\approx 1.4 \times 10^{17}$ and $\approx 0.7 \times 10^{17}$ cm$^{-2}$ for Sgr A* and GCS 3, respectively, with $\approx 70\%$ apolar in Sgr A* and $\approx 45\%$ apolar in GCS 3. As for the H$_2$O ice, Chiar et al. (2000) used the same SWS data discussed here but considered both the 6 and 3 $\mu$m water ice features to determine $N$(H$_2$O ice) $\approx 1.2 \times 10^{16}$ and $5 \times 10^{17}$ cm$^{-2}$ for Sgr A* and GCS 3, respectively. The high fraction of apolar CO ice and the high $N$(CO)/$N$(H$_2$O) ratios, together with the deep absorption of CO$_2$ ice (Whittet et al. 1997), are typical of cold, quiescent environments (Chiar et al. 1998), indicating that these ices cannot be located in the warm clouds in Sgr A West.

3.3. The Cold CO Gas

Because of the heavy saturation of the $^{12}$CO rovibrational lines (opacities of about 20–30), the physical parameters of the cold CO gas were determined from the $^{13}$CO and the adopted isotopic abundance ratio. Three components at the velocities indicated by the $J = 3–2$ absorption features in Figure 3 were used in the model, with line widths $\Delta v = 12$ km s$^{-1}$ as measured in our data. These line widths agree well with the results shown in Figure 1 of Sutton et al. (1990). The derived model parameters (column density and rotation temperature) are the same for the three components. Model results can be found in Table 1. A single C$^{18}$O velocity component was introduced in order to fit the weak $R(0)$ line of this isotope. We also find that in both lines of sight the cold gas alone is not sufficient to reproduce completely the $^{12}$CO absorption, and a component of higher kinetic temperature, $T = 40$ K, and $N = 1\%$ of the total, is necessary to account for the highest observed J lines. This component cannot arise from an incomplete removal of the warm gas in Sgr A West, since it is present in both spectra, and should correspond to dense cloud material [$n$(H$_2$) $> 5 \times 10^{15}$ cm$^{-3}$] of low CO column density. We estimate uncertainties of about a factor of 2 in the column densities. The volume density needed to pump the observed rotational levels of the CO ground state is around $3 \times 10^4$ cm$^{-3}$ in the case of $T_m = 10$ K (Sgr A*), decreasing to $\approx 1000$ cm$^{-3}$ at $T = 5$ K (GCS 3). Adopting $A_r/n$(H$_2$) $= 2 \times 10^{-21}$ mag cm$^{-2}$, the cold CO column densities imply visual extinction of 33 and 21 mag toward Sgr A* and GCS 3, respectively, generally consistent with values in the literature.

3.4. The Cold/Warm H$_2$O Gas

In contrast to CO, the H$_2$O absorption at 6 $\mu$m is weak: 3% (8 $\sigma$) in Sgr A* and 2% (3 $\sigma$) in GCS 3 (not shown). The three features detected are the $J_0=1-1$ (para) and the $J_0=2-1$ (ortho) lines of the $v_2 = 0 \rightarrow 1$ vibrational transition of water vapor (see Fig. 1f). In the Sgr A* data, the para transition is blended with the H$_2$ (0, 0) $S(6)$ line, which was removed by assuming an intensity of one-third the average of the $S(5)$ and $S(7)$ lines. The para line of H$_2$O is present before the subtraction of the $S(6)$ line of H$_2$; however, its intensity is poorly determined. All three absorption features arise from the ground para and ortho states to the first excited rotational levels of the bending mode of water vapor. The lack of other H$_2$O absorption features indicates that all the water molecules are in the ground state (ortho and para). An ortho/para abundance ratio of 3 has been assumed.

The best fit to the H$_2$O absorption, assuming also the three velocity components of CO, is obtained for $T_{rot} \approx 8$ K, similar to the temperatures deduced from CO. While these H$_2$O lines are not very sensitive to temperature in the 3–12 K range, an upper limit of $T_{rot} \leq 12$ K is obtained from the lack of ab-

![Figure 3](image-url)
absorption from the $1_{0\nu}$ ortho level, which is 26.7 K above the ortho ground state (absorption from other levels of para-water is more difficult as the first excited level, the $1_{1\nu}$, is 53.4 K above the para ground state). The rovibrational line opacities are $\approx 1$ and $\approx 0.3$ for the ortho and para species, respectively. The column density of H$_2$O is $2 \times 10^{26}$ cm$^{-2}$, with little dependence on the assumed $\Delta v$. This is due to the fact that line opacity and spectral dilution effects have inverse dependence on $\Delta v$ for optically thin ( $\tau$ below 1) lines.

The fact that the rotation temperature is low does not mean that the kinetic temperature is also low. While in the case of CO the inferred densities are high enough to make $T_{\text{rot}} = T_{\text{kin}}$, the same is not true for H$_2$O. In order to determine what fraction of the absorbing H$_2$O belongs to which temperature component, we used the LWS-FP spectrum of the $1_{10} - 2_{12}$ pure rotational line of ortho-H$_2$O (in the $\nu_2 = 0$ level) toward Sgr A* (see Fig. 3b). It indicates that the absorption arises from three different unresolved velocity components at $-30$, $-5$, and 45 km s$^{-1}$. The $1_{10} - 2_{12}$ line, on the other hand, shows significant absorption only at 45 km s$^{-1}$. This cloud is probably the one associated to Sgr A* itself, and as for Sgr B2 (Cernicharo et al. 1997b), the analysis of the water vapor data is much more difficult due to the role of dust emission/absorption in the excitation of this molecule. Taking into account the absolute velocity accuracy of the LWS-FP, the $-30$ and $-5$ km s$^{-1}$ features could correspond to the cold NH$_3$ (Serabyn & Güsten 1986) and CO $J = 3-2$ (see Fig. 3a). The CO absorption at $-55$ km s$^{-1}$ is marginal in the LWS-FP data of H$_2$O. For the physical conditions of the cold gas, a minimum opacity of $\approx 2$ with $\Delta v = 12$ km s$^{-1}$ is needed to produce the observed absorption. It corresponds to $N$(H$_2$O) $> 2 \times 10^{14}$ cm$^{-2}$. However, with this column density the contribution of the cold H$_2$O to the rovibrational absorption (SWS) will be negligible. Can we derive more precisely this column density? An answer can come from the different opacities of the pure rotational and rovibrational lines of H$_2$O.

The line profiles of the water transitions differ remarkably from those of the CO lines observed with the CSO (see Fig. 3a) and with the LWS-FP (not shown). The warm gas in Sgr A West could also produce a broad H$_2$O absorption, and such absorption would appear as a baseline effect in the reduced velocity coverage of the LWS-FP spectra. Such a baseline has been removed from our data, but it is not possible to infer the possible contribution of the warm gas from these data. The grating data (see inset panel in Fig. 3b), however, show an absorption feature 13% deep at the wavelength of the $1_{10} - 2_{12}$ line (and very weak absorption is also found for the $1_{10} - 2_{21}$ line), which would require 4 times the absorption produced by the narrow lines of Figure 3b. Therefore, most of the absorption found in the grating spectrum must correspond to a high velocity component badly detected with the LWS-FP. This broad absorption is also found in the 20 positions observed with the LWS grating spectrometer around Sgr A*.

The grating data suggest a line opacity of $\approx 1$ for a line width of 200 km s$^{-1}$. From the physical conditions we have derived for the warm gas, the $1_{10} - 2_{12}$ line opacity will be $\approx 1$ if $N$(H$_2$O) $= 10^{15}$ cm$^{-2}$. Hence, the H$_2$O abundance in the warm gas is $10^{-6}$, similar to that found in the warm foreground gas of Sgr B2 (Cernicharo et al. 1997b; Neufeld et al. 2000). However, this column density that explains well the absorption excess in the LWS grating data is insufficient to explain the SWS absorption. Hence, we have to assume that the cold gas must have a larger column density to account for the SWS data.

Removing the contribution from the warm gas, the total column density of cold H$_2$O must be $1.9 \times 10^{26}$ cm$^{-2}$ (three velocity components). The opacity and excitation temperature of the $1_{10} - 2_{12}$ rotational line will be $\approx 90$ and 7 K, respectively, for each one of the three velocity components assumed. For GCS 3 we obtain a cold H$_2$O column density of $\approx 1.2 \times 10^{26}$ cm$^{-2}$. These results suggest that the lines of sight intersect dense dark clouds where most of the absorption is produced. The $^{13}$CO/H$_2$O abundance ratio would be $\approx 5.8$ in both cases, i.e., $^{12}$CO/H$_2$O $= 350$. Hence, $X$(H$_2$O) $= 3 \times 10^{-7}$ and the water vapor gas/solid ratio is $\approx 0.02$ in the quiescent regions of dark clouds along the line of sight to the Galactic center.

The water vapor abundance in the dark clouds intersecting the line of sight of Sgr A* is much lower than that in the core of Sgr B2 and the shocked regions of Orion (see § 1). However, the total gas + ice CO/H$_2$O abundance ratio is $\approx 5$, which means that a large fraction of the H$_2$O molecules in these cold, quiescent regions is condensed on grains and that the chemical mechanisms leading to its formation (either in gas phase or in the grain surface) are very efficient and make H$_2$O the most abundant molecular species after CO.

The ISO data corresponding to the pure rotational lines of H$_2$O toward Sgr A* alone provide a lower limit for the water abundance of $\approx 10^{-8}$. However, when combining these data with the rovibrational H$_2$O lines also observed by ISO, a larger abundance, $\approx 10^{-7}$, is found. With this abundance, the pure $2_{12} - 1_{12}$ and $1_{10} - 1_{11}$ rotational lines of H$_2$O in the ground vibrational state will be extremely optically thick (see above), but the expected emission from these lines will remain very low. The upper limit to the water abundance derived through emission measurements by the Submillimeter Wave Astronomy Satellite (SWAS) in the direction of TMC-1 (7 $\times$ 10$^{-6}$; Snell et al. 2000) is only of factor of 4 lower than the value we derive in the dark clouds toward Sgr A*. If we consider that in dark clouds important scattering effects have to be taken into account in the radiative transfer of optically thick lines (see Cernicharo & Gülen 1987), the upper limit derived by SWAS could be slightly underestimated. Therefore, our results for Galactic dark clouds toward Sgr A* and SWAS results for TMC-1 will be in a relatively good agreement. Finally, absorption measurements toward continuum background sources at 556.9 GHz ($1_{10} - 1_{10}$) and at 179.526 and 269.273 $\mu$m ($1_{10} - 1_{12}$, and $0_{00} - 1_{11}$) with future satellite missions such as FIRST will provide a very efficient way to derive the water vapor abundance in dark clouds and in the diffuse interstellar medium.

We thank Spanish DGES for this research under grants PB96-0883 and ESP98-1351E. We thank E. González-Alfonso for useful comments. The CSO is supported by NSF grant AST 99-80846.
