Abstract—Attribute grammars allow the association of semantic actions to the production rules in context-free grammars, providing a simple yet effective formalism to define the semantics of a language. However, drafting the semantic actions can be tricky and a large drain on developer time. In this work, we propose a synthesis methodology to automatically infer the semantic actions from a set of examples associating strings to their meanings. We also propose a new coverage metric, derivation coverage. We use it to build a sampler to effectively and automatically draw strings to drive the synthesis engine. We build our ideas into our tool, PĀNINI, and empirically evaluate it on twelve benchmarks, including a forward differentiation engine, an interpreter over a subset of Java bytecode, and a mini-compiler for C language to two-address code. Our results show that PĀNINI scales well with the number of actions to be synthesized and the size of the context-free grammar, significantly outperforming simple baselines.

Index Terms—Program synthesis, Attribute grammar, Semantic actions, Syntax directed definition

I. INTRODUCTION

Attribute grammars [1] provide an effective formalism to supplement a language syntax (in the form of a context-free grammar) with semantic information. The semantics of the language is described using semantic actions associated with the grammar productions. The semantic actions are defined in terms of semantic attributes associated with the non-terminal symbols in the grammar.

Almost no modern applications use hand-written parsers anymore; instead, most language interpretation engines today use automatic parser generators (like YACC [2], BISON [3], ANTLR [4] etc.). These parser generators employ the simple, yet powerful formalism of attribute grammars to couple parsing with semantic analysis to build an efficient frontend for language understanding. This mechanism drives many applications like model checkers (eg. SPIN [5]), automatic theorem provers (eg. Q3B [6], CVC5 [7]), compilers (eg. CIL [8]), database engines (eg. MySQL [9]) etc.

However, defining appropriate semantic actions is often not easy: they are tricky to express in terms of the inherited and synthesized attributes over the grammar symbols in the respective productions. Drafting these actions for large grammars requires a significant investment of developer time.

In this work, we propose an algorithm to automatically synthesize semantic actions from sketches of attribute grammars.

Fig. 1 shows a sketch of an attribute grammar for automatic forward differentiation using dual numbers (we explain the notion of dual numbers and the example in detail in §III-A). The production rules are shown in green color while the semantic actions are shown in the blue color. Our synthesizer attempts to infer the definitions of the holes such that for all strings in the language described by the grammar, the computed semantic value (captured by the output construct) matches the intended semantics of the respective string—this is a new problem that cannot be trivially mapped to a program synthesis task.

This is a novel synthesis task: the current program synthesis tools synthesize a program such that a desired specification is met. In our present problem, we attempt to synthesize semantic actions within an attribute grammar: the synthesizer is required to infer definitions of the holes such that for all strings in the language described by the grammar, the computed semantic value (captured by the output construct) matches the intended semantics of the respective string—this is a new problem that cannot be trivially mapped to a program synthesis task.

Our core observation to solve this problem is the follows: for any string in the language, the sequence of semantic actions executed for the syntax-directed evaluation of any string is a loop-free program. This observation allows us to reduce attribute grammar synthesis to a set program synthesis tasks. Unlike a regular program synthesis task where we are interested in synthesizing a single program, the above reduction requires us to solve a set of dependent program

To the best of our knowledge, ours is the first work at automatic synthesis of semantic actions on attribute grammars. The following are our contributions in this work:

- We propose a new algorithm for synthesizing semantic actions in attribute grammars;
- We define a new coverage metric, derivation coverage, to generate effective examples for this synthesis task;
- We build our algorithms into an implementation, P\(\text{Āṇini}\), to synthesize semantic actions for attribute grammars;
- We evaluate P\(\text{Āṇini}\) on a set of attribute grammars to demonstrate the efficacy of our algorithm. We also undertake a case-study on the attribute grammar of the parser of the SP\(\text{IN}\) model-checker to automatically infer the constant-folding optimization and abstract syntax tree construction.

An extended version of this article is available [10]. The implementation and benchmarks of P\(\text{Āṇini}\) are available at https://github.com/pkalita595/P\(\text{Āṇini}\).

II. PRELIMINARIES

Attribute grammars [1] provide a formal mechanism to capture language semantics by extending a context-free grammar with attributes. An attribute grammar \(G\) is specified by \(\langle S, P, T, N, F, \Gamma \rangle\), where

- \(T\) and \(N\) are the set of terminal and non-terminal symbols (resp.), and \(S \in N\) is the start symbol;
- A set of (context-free) productions, \(p_i \in P\), where \(p_i : X_i \rightarrow Y_{i1}Y_{i2} \ldots Y_{in}\); a production consists of a head \(X_i \in N\) and body \(Y_{i1} \ldots Y_{in}\), such that each \(Y_{ik} \in T \cup N\);
- A set of semantic actions \(f_i \in F\);
- \(\Gamma : P \rightarrow F\) is a map from the set of productions \(P\) to the set of semantic actions \(f_i \in F\).

The set of productions in \(G\) describes a language (denoted as \(L(G)\)) to capture the set of strings that can be derived from \(S\). A derivation is a sequence of applications of productions \(p_i \in P\) that transforms \(S\) to a string, \(w \in L(G)\); unless specified, we will refer to the leftmost derivation where we always select the leftmost non-terminal for expansion in a sentential form. As we are only concerned with parsable grammars, we constrain our discussion in this paper to unambiguous grammars.

The semantic actions associated with the grammar productions are defined in terms of semantic attributes attached to the non-terminal symbols in the grammar. Attributes can be synthesized or inherited: while a synthesized attribute is computed from the children of a node in a parse tree, an inherited attribute is defined by the attributes of the parents or siblings.

Fig. 1 shows an attribute grammar with context-free productions and the associated semantic actions. Fig. 2 shows the parse tree of the string \(x^2 + 4x + 5\) on the provided grammar; each internal node of the parse tree has associated semantic actions (we have only shown the “unknown” actions that need to be inferred).
Can be captured by a tuple \( w \in L(G) \) and \( [w]_β^G = v \). A set of such examples constitutes an example suite (or test suite).

If the language described by the grammar \( G \) supports variables, then any evaluation of \( G \) needs a context, \( β \), that binds the free variables to input values. We denote such examples as \( [w]_β^G = v \). When the grammar used is clear from the context, we drop the superscript and simplify the notation to \( [w]_β = v \). Consider the example \( [x^r]_{x=2} = 8 + 12ε \), where “\( x^r \)” is a string from the grammar shown in Fig. 1 and the input string evaluates to \( 8 + 12ε \) under the binding \( x = 2 \). Clearly, if the language does not support variables, the context \( β \) is always empty.

### Problem Statement

Given a sketch of an attribute grammar, \( G^* \), an example set \( E \) and a domain-specific language (DSL) \( D \), synthesize instantiations of the holes by strings, \( w \in D \), such that the resulting attribute grammar agrees with all examples in \( E \).

In other words, PA\( NIN\)I synthesizes functions \( f_1, \ldots, f_n \) in the domain-specific language \( D \) such that the completion \( \tilde{G}^{\{f_1, \ldots, f_n\}} \) satisfies all examples in \( E \).

### A. Motivating example: Automated Synthesis of a Forward Differentiation Engine

We will use synthesis of an automatic forward differentiation engine using dual numbers [13] as our motivating example. We start with a short tutorial on how dual numbers are used for forward differentiation.

#### 1) Forward Differentiation using Dual numbers

Dual numbers, written as \( a + bε \), capture both the value of a function \( f(x) \) (in the real part, \( a \)), and that its differentiation with respect to the variable \( x \), \( f'(x) \), (in the dual part, \( b \))—within the same number. Clearly, \( a, b \in \mathbb{R} \) and we assume \( ε^2 = 0 \) (as it refers to the second-order differential, that we are not interested to track). The reader may draw parallels to complex numbers that are written as \( a + ib \), where ‘\( i \)’ identifies the imaginary part, and \( i^2 = -1 \).

Let us understand forward differentiation by calculating \( f'(x) \) at \( x = 3 \) for the function \( f(x) = x^2 + 4x + 5 \). First, the term \( x \) needs to be converted to a dual number at \( x = 3 \). For \( x = 3 \), the real part is clearly 3. To find the dual...
part, we differentiate the term with respect to variable $x$, i.e. \( \frac{dx}{dx} \) that evaluates to 1. Hence, the dual number representation of the term $x$ at $x = 3$ is $3 + 1\varepsilon$.

Now, dual value of the term $x^2$ can be computed simply by taking a square of the dual representation of $x$:

\[
(3 + 1\varepsilon)^2 = (3 + 1\varepsilon) \ast (3 + 1\varepsilon) = 3^2 + (2 \ast 3\varepsilon) + \varepsilon^2 = 9 + 6\varepsilon + 0
\]

Finally, the dual number representation for the constant 4 is $4 + 0\varepsilon$ (as differentiation of constant is 0). Similarly, the dual value for $4x$: $(4 + 0\varepsilon) \ast (3 + 1\varepsilon) = 12 + 4\varepsilon + 0$. So, we can compute the dual number for $f(x) = x^2 + 4x + 5$ as:

\[
(9 + 6\varepsilon) + (12 + 4\varepsilon) + (5 + 0\varepsilon) = 26 + 10\varepsilon
\]

Hence, the value of $f(x)$ at $x = 3$ is $f(3) = 26$ (real part of the dual number above) and that of its derivative, $f'(x) = 2x + 4$ is $f'(3) = 10$, which is indeed given by the the dual part for the dual number above.

2) **Synthesizing a forward differentiation engine:** The attribute grammar in Fig. 1 (adapted from [14]) implements forward differentiation for expressions in the associated context-free grammar; we will use this attribute grammar to illustrate our synthesis algorithm. lookUp($\Omega$, var) returns the value of the variable var from symbol table $\Omega$.

We synthesize programs for the required functionalities for the holes from the domain-specific language (DSL) shown in Equation 1. Function $\text{pow}(a, c)$ calculates $a$ raised to the power of $c$. We assume the availability of an input-output oracle, Oracle($\omega(\beta)$), that returns the expected semantic value for string $w$ under the context $\beta$.

\[
\text{Fun} ::= \text{C} + \text{C}\varepsilon
\]

\[
\text{C} ::= \text{var} \mid \text{num} \mid \text{C} \mid \text{C} + \text{C} \mid \text{C} - \text{C} \mid \text{C} \ast \text{C}
\]

\[
\mid \sin(\text{C}) \mid \cos(\text{C}) \mid \text{pow}(\text{C}, \text{num})
\]

(1)

\[
\begin{align*}
\text{B. Synthesis of semantic actions} \\
& \text{Our core insight towards solving this synthesis problem is that the sequence of semantic actions corresponding to the syntax-directed evaluation of any string on the attribute grammar constitutes a loop-free program.}
\end{align*}
\]

Fig. 5 shows the loop free program from the semantic evaluation of the example $\{\text{x}^2+4\ast\text{x}+5\}_{\text{x}=3} = 26 + 10\varepsilon$, the Hoare triple captures the synthesis constraints over the holes.

Similarly, our algorithm constructs constraints (as Hoare triples) over the set of all examples $E$ (e.g. $\{\text{x}+\text{x}\}_{\text{x}=13} = 26 + 2\varepsilon$, $\{\text{3-x}\}_{\text{x}=7} = -4 - 1\varepsilon$, $\{\text{x}+\text{x}\}_{\text{x}=4} = 16 + 8\varepsilon$, $\{\sin(\text{x}^2)\}_{\text{x}=3} = 0.41 - 5.47\varepsilon$).

\[
\begin{align*}
\{\cos(x^2)\}_{x=2} &= -0.65 + 3.02\varepsilon, \\
\{\text{x}\ast\cos(x)\}_{x=4} &= -2.61 + 2.37\varepsilon.
\end{align*}
\]

Synthesizing definitions for holes that satisfy Hoare triple constraints of all the above examples yields a valid completion of the sketch of the attribute grammar (see Fig. 3). As the above queries are “standard” program synthesis queries, they can be answered by off-the-shelf program synthesis tools [15, [16]. Hence, our algorithm reduces the problem of synthesizing semantic actions for attribute grammars to solving a conjunction of program synthesis problems.

While the above conjunction can be easily folded into a single program synthesis query and offloaded to a program synthesis tool, quite understandably, it will not scale. To scale the above problem, we employ a refutation-guided inductive synthesis procedure: we sort the set of examples by increasing complexity, completing the holes for the easier instances first. The synthesized definitions are frozen while handling new examples; however, unsatisfiability of a synthesis call with frozen procedures refutes the prior synthesized definitions. Say we need to synthesize definitions for $\{h_1, \ldots, h_6\}$ and examples $\{e_1, \ldots, e_{i-1}\}$ have already been handled, with definitions $\{h_1 = f_1, \ldots, h_5 = f_5\}$ already synthesized. To handle a new example, $e_i$, we issue a synthesis call for procedures $\{h_6, \ldots, h_9\}$ with definitions $\{h_6 = f_1, \ldots, h_8 = f_8\}$ frozen. Say, the constraint corresponding to $e_i$ only includes calls $\{h_7, h_8\}$ and the synthesis query is unsatisfiable. In this case, we unfreeze only the participating frozen definitions (i.e. $\{h_7, h_8\}$) and make a new synthesis query. As new query only attempts to synthesize a few new calls (with many participating calls frozen to previously synthesized definitions), this algorithm scales well.

For example, consider the grammar in Fig. 1: the loop-free program resulting from the semantic evaluation of the input $\{\text{x}+\text{x}\}_{\text{x}=13} = 26 + 2\varepsilon$ (say trace $t_1$) includes only one $h_1$. Hence, we synthesize $h_1$ with only the constraint $\{x = 13\}t_1(\text{output} = 26 + 2\varepsilon)$, that results in the definition shown in Fig. 3a. Next, we consider the input $\{\text{x}+\text{x}\}_{\text{x}=4} = 16 + 8\varepsilon$, its constraint includes the holes $h_3$, which is synthesized as the definition function shown in Fig. 4. Now, with $\{h_1, h_2\}$ frozen to their respective synthesized definitions, we attempt to handle $\{\text{x}\ast\cos(x)\}_{\text{x}=4} = -2.61 + 2.37\varepsilon$. Its constraint includes the holes $\{h_7, h_8\}$; now we only attempt to synthesize $h_6$ while constraining $h_3$ to use the definition in Fig. 4.

Fig. 5: Hoare triple constraint for $x^2 + 4x + 5$ at $x = 3$
In this case the synthesizer fails to synthesize $h_6^*$ since the synthesized definition for $h_6^*$ is incorrect, thereby refuting the synthesized definition of $h_3^*$. Hence, we now unfreeze $h_3^*$ and call the synthesis engine again to synthesize both $h_3^*$ and $h_6^*$ together. This time we succeed in inferring correct synthesized definition as shown in Fig. 3.

C. Example Generation

We propose a new coverage metric, derivation coverage, to generate good samples to drive synthesis. Let us explain derivation coverage with an example. $[[x^2 + 4x + 5]]_{x=3}$ from the grammar in Fig. 1. The leftmost derivation of this string covers eight productions, $\{1, 2, 4, 5, 6, 7, 8, 10, 11\}$ out of a total of 11 productions. Intuitively, it implies that the Hoare triple constraint from its semantic evaluation will test the semantic actions corresponding to these productions.

Similarly, the Hoare logic constraint from the example $[[x^2 + 7x + \sin(x)]]_{x=2}$ will cover 9 of the productions, $\{1, 2, 4, 5, 6, 7, 8, 10, 11\}$. As it also covers the semantic action for the production 8, it tests an additional behavior of the attribute grammar. On the other hand, the example $[[x^2 + 3x + 5x]]_{x=5}$ invokes the productions, $\{1, 2, 4, 5, 6, 7, 10, 11\}$. As all these semantic actions have already been covered by the example $[[x^2 + 4x + 5]]_{x=3}$, it does not include the semantic action of any new set of productions.

In summary, derivation coverage attempts to abstract the derivation of a string as the set of productions in its leftmost derivation. It provides an effective metric for quantifying the quality of an example suite and also for building an effective example generation system.

Validation. Our example generation strategy can start off by sampling strings $w$ from the grammar (that improve derivation coverage), and context $\beta$; next, it can query the oracle for the intended semantic value $v = \text{Oracle}(w(\beta))$ to create an example $[[w]]^G_{\beta} = v$.

Consider that the algorithm finds automatically an example $[[x^2 + 4x + 5]]_{x=3}$. Now, there are two possible, semantically distinct definitions that satisfy the above constraint (see Fig. 3c and Fig. 4), indicating that the problem is underconstrained. Hence, our system needs to select additional examples to resolve this. One solution is to sample multiple contexts on the same string to create multiple constraints:

- $\{x = 2\}$ $k_1$.val $\leftarrow 2 + 1\varepsilon; \ldots$ $\{\text{output} = 13 + 6\varepsilon\}$
- $\{x = 4\}$ $k_1$.val $\leftarrow 4 + 1\varepsilon; \ldots$ $\{\text{output} = 29 + 10\varepsilon\}$

The above constraints resolve the ambiguity and allows the induction of a semantically unique definitions. The check for semantic uniqueness can be framed as a check for distinguishing inputs: given a set of synthesized completion $G^s(f_1, \ldots, f_n)$, we attempt to synthesize an alternate completion $G^s(g_1, \ldots, g_n)$ and an example string $w$ (and context $\beta$) such that $[[w]]^s_{\beta} \neq [[w]]^s_{\beta}$. In other words, for the same string (and context), the attribute grammar returns different evaluations corresponding to the two completions. For example, $[[x^2 + 4x + 5]]_{x=2}$ is a distinguishing inputs witnessing the ambiguity between the definitions shown in Fig. 3c and Fig. 4.

On the other hand, the algorithm could have sampled other strings (instead of contexts) for additional constraints. PĂNINI prefers the latter; that is, it first generates a good example suite (in terms of derivation coverage) and only uses distinguishing input as a validation (post) pass. If such inputs are found, additional contexts are added to resolve the ambiguity.

We provide the detailed algorithm of example generation in the extended version [10].

IV. ALGORITHM

Given an attribute grammar $G^*$, a set of holes $h_i \in H$, a domain-specific language $D$, an example suite $E$ and a context $\beta$, PĂNINI attempts to find instantiations $g_i$ for $h_i$ such that,

$$\text{Find}(g_1, \ldots, g_H) \in D \text{ such that } \forall (s, \beta, v) \in E. [[s]]^G_{\beta} = v$$

where the attribute grammar $G = G^*[g_1/h_1, \ldots, g_H/h_H]$ and variable bindings $\beta$ maps variables in $s$ to values.

A. Basic Scheme: ALLATÒNCE

Our core synthesis procedure (Algorithm 1), SYNT-HOLES($G^*$, $E$, $R$, $D$), accepts a sketch $G^*$, an example (or test) suite $E$, a set of ready functions $R$ and a DSL $D$; all holes whose definitions are available are referred to as ready functions. When SYNT-HOLES is used as a top-level procedure (as in the current case), $R = \emptyset$; if not empty, the definitions of the ready functions are substituted in the sketch $G^*$ to create a new sketch $G^*_R$ on the remaining holes (Line 2).

We refer to the algorithm where $R = \emptyset$ at initialization as the ALLATÒNCE algorithm.

Our algorithm exploits the fact that a syntax-directed semantic evaluation of a string $w$ on an attribute grammar $G$ produces a loop-free program. It attempts to compute a symbolic encoding of this program trace in the formula $\varphi$ (initialized to $\text{true}$ in Line 1). GENTRACE() instruments the semantic evaluation on the string $w$ to collect a symbolic trace (the loop-free program) consisting of the set of instructions encountered during the syntax-directed execution of the attribute grammar (Line 4); an output from an operation that is currently a hole is appended as a symbolic variable. The assertion that the expected output $v$ matches the final symbolic output $\text{out}(t)$ from the trace $t$ is appended to the list of constraints (Line 5). Finally, we use a program synthesis procedure, Synthesize with the constraints $\varphi$ in an attempt to synthesize suitable function

Algorithm 1: SYNTHHOLES($G^*$, $T$, $R$, $D$)

1. $\varphi \leftarrow \top$
2. $G^*_R \leftarrow G^*[R]$
3. for $(w, v) \in T$ do
   4. $t \leftarrow \text{GENTRACE}(\llbracket w \rrbracket^G_{\varphi})$
   5. $\varphi \leftarrow \varphi \land (\text{out}(t) = v)$
6. $B \leftarrow \text{SYNTHESIZE}(\varphi, D)$
7. return $B$

308
definitions for the holes in $\varphi$ (Line 6). Given a constraint in terms of a set of input vector $\vec{x}$ and function symbols (corresponding to holes) $\vec{h}$, we use an example from forward differentiation (Fig. 1) to illustrate this. Let us consider two inputs, $\left\{[x^2-2*x]_{x=3} = 3 + 4\varepsilon\right\}$ and $\left\{[3*x+6]_{x=2} = 12 + 3\varepsilon\right\}$. For the first input, the procedure GENTRACE() (Line 4) generates a symbolic trace (denoted $t_1$):

$$x_1 = 2 + 1\varepsilon; \alpha_1 = h^*_1(3+0\varepsilon, x_1); out_{t_1} = h^*_1(\alpha_1, 6+0\varepsilon);$$

The following symbolic constraint is generated from above trace:

$$\varphi_{t_1} \equiv (x_1 = 2 + 1\varepsilon \land \alpha_1 = h^*_1(3+0\varepsilon, x_1) \land out_{t_1} = h^*_1(\alpha_1, 6))$$

In the trace $t_1$, operators $h^*_1$ and $h^*_3$ are holes and variables, i.e., $\alpha_1$, $out_{t_1}$ are the fresh symbolic variables. In the next step (line 5), the constraints generated from trace $t_1$ is added, $\varphi \equiv T \land (\varphi_{t_1} \land out_{t_1} = 12 + 3\varepsilon)$

In the next iteration of the loop at line 3, the algorithm will take the second input, (i.e., $\left\{[x^2-2*2*x]_{x=3} = 3 + 4\varepsilon\right\}$). In this case, GENTRACE() will generate following trace ($t_2$),

$$\{x_2 = 3 + 1\varepsilon; \alpha_2 = h^*_1(x_2, 2); \alpha_3 = h^*_1(2 + 0\varepsilon, x_2); out_{t_2} = h^*_2(\alpha_3, \alpha_4)\}$$

The generated constraints from $t_2$ will be,

$$\varphi_{t_2} \equiv (x_2 = 3 + 1\varepsilon \land \alpha_2 = h^*_1(x_2, 2) \land \alpha_3 = h^*_1(2 + 0\varepsilon, x_2) \land out_{t_2} = h^*_2(\alpha_3, \alpha_4))$$

At line 5, new constraints will be,

$$\varphi \leftarrow T \land (\varphi_{t_1} \land out_{t_1} = 12 + 3\varepsilon) \land (\varphi_{t_2} \land out_{t_2} = 3 + 4\varepsilon)$$

At line 6, with $\varphi$ as constraints, the algorithm will attempt to synthesize definitions for the holes (i.e., $h^*_1$, $h^*_2$, $h^*_3$ and $h^*_4$).

**B. Incremental Synthesis**

The ALLATONCE algorithm exhibits poor scalability with respect to the size of the grammar and the number of examples. The route to a scalable algorithm could be to incrementally learn the definitions corresponding to the holes and make use of the functions synthesized in the previous steps to discover new ones in the subsequent steps.

However, driving synthesis one example at a time will lead to overfitting. We handle this complexity with a two-pronged strategy: (1) we partition the set of examples by the holes for which they need to synthesize actions, (2) we solve the synthesis problems by their difficulty (in terms of the number of functions to be synthesized) that allows us to memoize their results for the more challenging examples. We refer to this example as the INCREMENTALSYNTHESIS algorithm.

| Algorithm 2: SYNTHATTRGRAMMAR($G^*$, E, D) |
|---|
| 1 $T \leftarrow \emptyset$;  |
| 2 $R \leftarrow \emptyset$;  |
| 3 while $T \neq E$ do  |
| 4 $(w, v) \leftarrow \text{SELECTEXAMPLE}(E \setminus T)$;  |
| 5 $Z \leftarrow \text{GETSKETCHYPRODS}(G^*, w)$;  |
| 6 if $Z \subseteq R$ then  |
| 7 $G^* \leftarrow G^*[R]$;  |
| 8 if $[w]_{G^*} = v$ then  |
| 9 $T \leftarrow T \cup \{(w, v)\}$;  |
| 10 continue;  |
| 11 else  |
| 12 $R \leftarrow R \setminus Z$;  |
| 13 $T_e \leftarrow T \cup \{(w, v)\}$;  |
| 14 else  |
| 15 $T_e \leftarrow \{(w_i, v_i) \mid w \equiv w_i, (w_i, v_i) \in E\}$;  |
| 16 $B \leftarrow \text{SYNTHHOLES}(G^*, T_e, R, D)$;  |
| 17 if $B = \emptyset$ then  |
| 18 $R_f \leftarrow \emptyset$;  |
| 19 $R \leftarrow R \cup R_f$;  |
| 20 $T \leftarrow T \cup T_e$;  |
| 21 return $R$;  |

**Derivation Congruence.** We define an equivalence relation, derivation congruence, on the set of strings $w \in L(G)$: strings $w_1, w_2 \in L(G)$ are said to be derivation congruent, $w_1 \equiv_G w_2$ w.r.t. the grammar $G$, if and only if both the strings $w_1$ and $w_2$ contain the same set of productions in their respective derivations. For example, $w_1 : [3*x+5]_{x=2}$, $w_2 : [5*x+12]_{x=3}$ and $w_3 : [4*x+7*x]_{x=3}$.

Note that though the strings $w_1$, $w_2$ and $w_3$ are derivation congruent to each other, while $w_1$ and $w_2$ have similar parse trees, $w_3$ has a quite different parse tree. So, intuitively, all these strings are definition congruent to each other, as, even with different parse trees, they involve the same set of productions ($\{1, 2, 4, 5, 6, 10, 11\}$) in their leftmost derivation.

Algorithm 2 shows our incremental synthesis strategy. Our algorithm maintains a set of examples (or tests) $T$ (line 2) that are consistent with the current set of synthesized functions for the holes; the currently synthesized functions (referred to as _ready_ functions), along with the respective ready productions, are recorded in $R$ (line 1). The algorithm starts off by selecting the _easiest_ example $(w, v)$ at line 4 such that the cardinality of the set of sketchy production, $Z$, in the derivation of $w$ is the minimal among all examples not in $T$. The set $R$ maintains a map from the set of sketchy productions to a set of assignments to functions synthesized (instantiations) for each hole contained in the respective semantic actions.

If all sketchy productions, $Z$, in the derivation of $w$ are now ready, we simply test (line 6) to check if a syntax-guided evaluation with the currently synthesized functions in
If the algorithm terminates with a non-empty set of definitions in $R$, the provided domain-specific language fails too, it implies that no instantiation of the holes exist in $w$ (line 19) and re-attempt synthesis (line 20). If this attempt fails too, it implies that no instantiation of the holes exist in the provided domain-specific language $D$ (line 22).

We provide a detailed example on the run of this algorithm in the extended version [10].

**Theorem.** If the algorithm terminates with a non-empty set of functions, $G^*$ instantiated with the synthesized functions will satisfy the examples in $E$; that is, the synthesized functions satisfy Equation 2.

The proof is a straightforward argument with the inductive invariant that at each iteration of the loop, the $G^*$ instantiated with the functions in $R$ satisfy the examples in $T$.

**V. EXPERIMENTS**

Our experiments were conducted in Intel(R) Xeon(R) CPU E5-2620 @ 2.00GHz with 32 GB RAM and 24 cores on a set of benchmarks shown in Table I. PÄÑINI uses FLEX [17] and BISON [3] for performing a syntax-directed semantic evaluation over the language strings. PÄÑINI uses SKETCH [15] to synthesize function definitions over loop-free programs, and the symbolic execution engine CREST [18] for generating example-suites guided by derivation coverage.

We attempt to answer the following research questions:

- Can PÄÑINI synthesize attribute grammars from a variety of sketches?
- How do INCREMENTALSYNTHESIS and ALLATONCE algorithms compare?
- How does PÄÑINI scale with the number of holes?
- How does PÄÑINI scale with the size of the grammar?

The default algorithm for PÄÑINI is the INCREMENTALSYNTHESIS algorithm; unless otherwise mentioned, PÄÑINI refers to the implementation of INCREMENTALSYNTHESIS (Algorithm 2) for synthesis using examples generation guided by derivation coverage (detailed explanation available in the extended version [10]). While ALLATONCE works well for small grammars with few examples, INCREMENTALSYNTHESIS scales well even for larger grammars, both with the number of holes and size of the grammar.

PÄÑINI can synthesize semantic-actions across both synthesized and inherited attributes. Some of our benchmarks contain inherited-attributes: for example, benchmark b8 uses inherited-attributes to pass the type information of the variables. Inherited-attributes pose no additional challenge; they are handled by the standard trick of introducing “marker” non-terminals [19].

**A. Attribute Grammar Synthesis**

We evaluated PÄÑINI on a set of attribute grammars adapted from software in open-source repositories [14], [19]–[24]. Table I shows the benchmarks, number of productions (#P), number of holes (#H), input example, solving time (Time), AAO for ALLATONCE and IS for INCREMENTALSYNTHESIS) and number of times a defined function was refuted (|R|). Please recall that ALLATONCE refers to Algorithm 1 (§IV-A) and INCREMENTALSYNTHESIS refers to Algorithm 2 (§IV-B).

We provide more detailed descriptions of the benchmarks b1 to b9 in the extended version [10]. The benchmark b10 is the forward differentiation example described in §III-A. Benchmarks b11 and b12 are quite complex benchmarks that interpret a (subset) of Java bytecode and compile C code:

**b11 Bytecode interpreter.** Interpreter for a subset of Java bytecode; it supports around 36 instructions [25] of different type, i.e., load-store, arithmetic, logic and control transfer instructions.

**b12 Mini-compiler.** Fig. 6 shows the different steps of synthesizing semantic actions in mini-compiler. Fig. 6b is a sample input for the mini-compiler. Fig. 6a shows snippet of the attribute grammar for mini-compiler. Fig. 6c shows the two-address code generated from the input code shown in Fig. 6b, where $h_u^*$ and $h_s^*$ are two holes in the two-address code. Finally, in Fig. 6d shows the synthesized definition for $h_u^*$ and $h_s^*$ in the target language for two-address code.

Fig. 8 attempts to capture the fraction of time taken by the different phases of PÄÑINI: example generation and synthesis. Not surprisingly, the synthesis phase dominates the cost as it requires several invocation of the synthesis engines, whereas, the example generation phase does not invoke synthesis engines or smt solvers. Further, the difference in time spend in these two phases increases as the benchmarks get more challenging.

**B. ALLATONCE v/s INCREMENTALSYNTHESIS**

1) **Scaling with holes:** Fig. 9a and Fig. 9b show PÄÑINI scales with the sketches with increasingly more holes. We do this study for forward differentiation (b10) and bytecode interpreter (b11). As can be seen, PÄÑINI scales very well. On the other hand, ALLATONCE works well for small instances but soon blows up, timing out on all further instances. The interesting jump in b10 (at #Holes=8) was seen when we...
S → MAIN B
... Σ → T
  | E + T A.val = h^a(E.val, T.val);
  | E - T A.val = h^a(E.val, T.val);
T → T
  | T * F T.val = h^a(T.val, F.val);
  | T / F T.val = h^a(T.val, F.val);
... (a) Attribute grammar sketch for mini-compiler

Action synthesis

TABLE I: Description of benchmarks

| Id | Benchmark            | #P | #H | Example                  | #R | Time (s) | AAO | BS |
|----|----------------------|----|----|--------------------------|----|----------|-----|-----|
| b1 | Count ones           | 5  | 1  | 11001                    | 0  | 3.2      | 3.1 |
| b2 | Binary to integer    | 5  | 1  | 01110                    | 0  | 3.6      | 2.9 |
| b3 | Prefix evaluator     | 7  | 4  | + 3 4                    | 0  | TO       | 10.1|
| b4 | Postfix evaluator    | 7  | 4  | 2*3 4 +                   | 0  | TO       | 10.5|
| b5 | Arithmetic calculator| 8  | 4  | b * 2 + 8                | 0  | TO       | 12.8|
| b6 | Currency calculator  | 10 | 4  | USDA 3 + 1BR 8           | 0  | TO       | 13.6|
| b7 | if-else calculator   | 10 | 4  | if(3+4 == 3) then 44;    | 1  | TO       | 21.7|
| b8 | Activation record layout | 10 | 3  | int a, b;                | 0  | TO       | 13.8|
| b9 | Type checker         | 11 | 5  | (5 - 2) == 3            | 1  | TO       | 15.4|
| b10| Forward differentiation | 20 | 12 | k.pow(x, 3)             | 2  | TO       | 39.2|
| b11| Bytecode interpreter | 39 | 36 | bipush 3; bipush 4; iadd; | 3  | TO       | 141.4|

(b) A simple C code

```c
int main()
{
    int a, b, c;
    a = 4;
    b = a + 3; /* h^a
    c = a - b; /* h^a
    return c;
}
```

(c) Three-address code generated from C code in Fig. 6b

```
assign 4 a
assign 10 b
t0 T0
assign 73 a b T1
t1 T1
t2 T2
```

(d) Synthesized definition for h^a, h^b

```
init {
    run Foo(8+(6-7));
}
```

(e) PROMELA source code

```
node n1 = node(val=8);
node n2 = node(val=6);
node n3 = node(val=7);
node n4 = h^a(n2, n3);
node n5 = h^a(n1, n4);
node n6 = h^c(’Foo’, n5);
```

(f) Trace generated

```
Fig. 6: Synthesis of mini-compiler (b12)
```

Fig. 7: Trace generation for AST construction

Fig. 8: Stacked bar graph for the % time spent in example creation

started adding holes for the definitions of the more complex operators like sin() and cos().

2) Scaling with size of grammar: Table I shows that INCREMENTAL.SYNTHESIS scales well with the size of the grammar (by the number of productions). On the other hand, ALLATONCE works well for the benchmarks b1 and b2 as they have only one hole while it times out for the rest.

The complexity of INCREMENTAL.SYNTHESIS is independent of the size of the attribute-grammar but dependent on the length of derivations and the size of the semantic actions. The current state of synthesis-technology allows PĂNINİ to synthesize practical attribute grammars that have a large number of productions but mostly “small” semantic actions and where short derivations can “cover” all productions. Further, any improvement in program-synthesis technology automatically improves the scalability of PĂNINİ.

VI. CASE STUDY

We undertook a case-study on the parser specification of the SPIN [5] model-checker. SPIN is an industrial-strength model-checker that verifies models written in the PROMELA [26] language against linear temporal logic (LTL) specifications. SPIN uses YACC [2] to build its parser for PROMELA.

The modelling language, PROMELA, is quite rich, supporting variable assignments, branches, loops, arrays, structures, procedures etc. The attribute grammar specification in the YACC language is more than 1000 lines of code (ignoring newlines) having 280 production rules.

The semantic actions within the attribute grammar in the YACC description handle multiple responsibilities. We selected two of its operations:
(b) Java bytecode (b11)

Fig. 9: #Hole v/s Time for benchmarks b10 and b11

a) Constant folding array indices: As the PROMELA code is parsed, semantic actions automatically constant-fold array indices (see Fig. 10). We removed all the actions corresponding to constant-folding by inserting 8 holes in the relevant production rules (these correspond to the non-terminal const_expr). The examples to drive the synthesis consisted of PROMELA code with arrays with complex expressions and the target output was the optimized PROMELA code. PĂȘINI was able to automatically synthesize this constant-folding optimization within less than 4 seconds.

b) AST construction: A primary responsibility of the semantic analysis phase is to construct the abstract syntax tree (AST) of the source PROMELA code. We, next, attempted to enquire if PĂȘINI is capable of this complex task.

In this case, each example includes a PROMELA code as input and a tree (i.e. the AST) as the output value. We removed the existing actions via 23 holes. These holes had to synthesize the end-to-end functionality for a production rule with respect to building the AST: that, the synthesized code would decides the type of AST node to be created and the correct order of inserting the children sub-trees.

Run of the example suite on the sketchy productions generates a set of programs (one such program shown in Fig. 7); these programs produce symbolic ASTs that non-deterministically assigns type to nodes and assigns the children nodes. We leverage the support of references in Sketch to define self-referential nodes.

We insert constraints that establish tree isomorphism by recursively matching the symbolic ASTs with the respective output ASTs (available in example suite); for example, in Fig. 11 isomorphism constraints are enforced on the concrete and the symbolic ASTs. Sketch resolves the non-determinism en route to synthesizing the relevant semantic actions. In this case-study, PĂȘINI was able to synthesize the actions corresponding to the 23 holes within 20 seconds.

VII. RELATED WORK

Program synthesis is a rich area with proposals in varying domains: bitvectors [27], [28], heap manipulations [29]–[33], bug synthesis [34], differential privacy [35], [36], invariant generation [37], Skolem functions [38]–[40], synthesis of fences and atomic blocks [41] and even in hardware security [42]. However, to the best of our knowledge, ours is the first work on automatically synthesizing semantics actions for attribute grammars.

There has some work on automatically synthesizing parsers: PARSIYF [43] provides an interactive environments to automatically infer grammar rules to parse strings; it is been shown to synthesize grammars for Verilog, Tiger, Apache Logs, and SQL. CYCLOPS [44] builds an encoding for Parse Conditions, a formalism akin to Verification Conditions but for parseable languages. Given a set of positive and negative examples, CYCLOPS, automatically generates an LL(1) grammar that accepts all positive examples and rejects all negative examples. Though none of them handle attribute grammars, it may be possible to integrate them with PĂȘINI to synthesize both the context-free grammar and the semantic actions. We plan to pursue this direction in the future.

We are not aware of much work on testing attribute grammars. We believe that our derivation coverage metric can also be potent for finding bugs in attribute grammars, and can have further applications in dynamic analysis [45]–[47] and statistical testing [48], [49] of grammars. However, the effectiveness of this metric for bug-hunting needs to be evaluated and seems to be a good direction for the future.
