We study the scaling regime of hadron - (anti)-hadron annihilation into a deeply virtual photon and a real photon, \(\bar{H}H \rightarrow \gamma^* \gamma\), and backward virtual Compton scattering, \(\gamma^* H \rightarrow H \gamma\). We advocate that there is a kinematical region where the scattering amplitude factorizes into a short-distance matrix element and a long-distance dominated object : a transition distribution amplitude which describes the hadron to photon transition.

1. Introduction
There now exists a successful description of deep exclusive reactions in terms of distribution amplitudes [1] and/or generalized parton distributions [2] on the one side and perturbatively calculable coefficient functions describing hard scattering at the partonic level on the other side. The pioneering papers [1] and [3] have opened the way to a real understanding of many processes that share with hadronic form factors and deeply virtual Compton scattering (dVCS) in the nearly forward region some basic properties and in particular the factorization [4] of the long distance dominated matrix element of the non-local correlator of two quark or gluon fields between two hadronic states. Many processes have been studied in this framework [5]. Cases have been studied where the generalized parton distribution (GPD) describes the transition of a nucleon to a nucleon, to a resonance [6], a nucleon-meson continuum state [7] or the exotic pentaquark [8]. We consider here a somewhat different class of reaction, where the t-channel exchange carries most of the quantum numbers of the hadron. The simplest examples are the annihilation:

\[
\bar{p}p \rightarrow \gamma^* \gamma \rightarrow e^+e^- \gamma
\]  

in the near forward region and large virtual photon invariant mass \(Q\) which will be studied in detail at GSI [9], and the VCS reaction in the backward region (i.e. when the real photon is emitted in the direction of the proton momentum in the CM system)

\[
\gamma^* p \rightarrow p \gamma\, ,
\]

which is currently under experimental investigation at JLab [10].

The crucial observation that we want to make is that the amplitude for the process [1] is quite analogous to the one for process [3]

\[
\bar{p}p \rightarrow \gamma^* \rightarrow e^+e^- \quad \gamma^* p \rightarrow p\, ,
\]

which are controlled by the timelike and spacelike proton form factors, respectively, the asymptotic form of which may be calculated in QCD [1], through the factorization of proton and antiproton distribution amplitudes on the one hand, and the hard processes \(qqggq \rightarrow \gamma^*\) or \(\gamma^*qqq \rightarrow qqq\) on the other hand. The only change needed is to replace the proton distribution amplitude which is defined from the correlator \(\langle 0|u(z_1)u(z_2)d(z_3)|p\rangle\) by a quantity derived from a slightly different matrix element of the same operator, i.e. the correlator \(\langle \gamma|u(z_1)u(z_2)d(z_3)|p\rangle\). This symbolic notation omits the gauge links between quarks and their spin and colour indices.

This is what we define, see Fig. 1, as the hadron to photon transition distribution amplitude (TDA), which enters in the expression of the amplitude for process [1] in the kinematical region where hard and soft processes decouple, namely when the real photon momentum is almost collinear to the incoming \((\pi^+\) or \(p\) in Fig. 1) hadron momentum as in the case of QCD factorization in dVCS. An other useful reaction of reference is the reaction \(\pi^-p \rightarrow \gamma^* n\) [11], which has been analysed in the framework of QCD factorization. If we restrict this reaction to a meson target, the obtained reaction \(\pi^-\pi^+ \rightarrow \gamma^* \pi^0\) looks much the same as the one we consider here. One can apply to this last process the proof of factorization given in Ref. [4] for the vector meson.
production \[20\].

Such an extension of the factorization proof has already been briefly advocated in Ref. \[12\] for the electroproduction of leading baryons or antibaryons. As was advocated there, factorization in hard exclusive processes such as \(\gamma_{\ell}p \rightarrow pp'\) is basically due to the fact that the meson originates from a small size \(qq\) object which is generated by a hard scattering (the hardness of the scattering controlling the initial size of the color singlet). In the case under study, the only difference is that the small size \(qqq\) object carries baryon number.

In this letter, we shall restrict to the case of spinless hadrons, and study the reactions

\[
\pi^- \pi^+ \rightarrow \gamma^* \gamma, \quad \gamma^* \pi^+ \rightarrow \pi^+ \gamma, \quad (4)
\]

with a few qualitative comments on the extension of this analysis to the phenomenologically more interesting proton case, which will be studied in detail in a future work. We also restrict to the longitudinal polarization of the virtual photon.

2. The \(H \rightarrow \gamma\) transition distribution amplitude

Let us take a closer look at the transition distribution amplitudes that occur in the processes we are interested in. For their definition we introduce light-cone coordinates \(v^\pm = (v^0 \pm v^3)/\sqrt{2}\) and transverse components \(v_T = (v^1, v^2)\) for any four-vector \(v\). The skewness variable \(\xi = (p - p')^z/2P^z + P = (p + p')/2\) describes the loss of plus-momentum of the incident hadron. The momentum transfer is \(\Delta = p' - p\).

We define the corresponding \(H \rightarrow \gamma\) leading twist TDAs in the mesonic case as \((\varepsilon\) is the polarization of a photon\):

\[
\int \frac{dz}{2\pi} e^{izP^z} \langle\gamma(p', \varepsilon)|O_V^\mu|\pi^+(p)\rangle \bigg|_{z=0, z_T=0} = \frac{1}{P_T} \int \frac{d\xi}{f_\pi} \varepsilon_{\perp} P_{\perp} \Delta_{\perp} V(x, \xi, t) \quad O_V^\mu = \bar{d}(z/2)\gamma^\mu u(z/2)
\]

(5)

\[
\int \frac{dz}{2\pi} e^{izP^z} \langle\gamma(p', \varepsilon)|O_A^\mu|\pi^+(p)\rangle \bigg|_{z=0, z_T=0} = \frac{1}{P_T} \int \frac{d\xi}{f_\pi} (\varepsilon \cdot \tilde{\Delta}) P^\mu A(x, \xi, t) \quad O_A^\mu = \bar{d}(z/2)\gamma^\mu_5 u(z/2)
\]

(6)

\[
\int \frac{dz}{2\pi} e^{izP^z} \langle\gamma(p', \varepsilon)|O_T^\mu|\pi^+(p)\rangle \bigg|_{z=0, z_T=0} = \frac{1}{P_T} \int \frac{d\xi}{f_\pi} \varepsilon_{\perp} \rho T_1(x, \xi, t) - \frac{1}{f_\pi}(\varepsilon \cdot \tilde{\Delta}) \Delta_{\perp} T_2(x, \xi, t)
\quad O_T^\mu = \bar{d}(z/2)\sigma^\mu_\perp u(z/2),
\]

(7)

where the first two TDAs, \(V(x, \xi, t)\) and \(A(x, \xi, t)\) are chiral even and the latter ones, \(T_i(x, \xi, t), i = 1, 2\), are chiral odd. In definitions \[13\], \[9\] and \[14\] it is assumed that like in the usual GPDs a Wilson link along the light-cone is included to ensure the QCD-gauge invariance for non local operators. We omit this link to simplify the notation. \(f_\pi\) is the pion decay constant. The four leading twist TDAs are linear combinations of the four independent helicity amplitudes for the process \(\gamma \pi \rightarrow q\gamma\).

As in the case of GPDs, the signs of \(x \pm \xi\) determine the partonic interpretation of the TDAs. One thus distinguishes in a completely analogous with usual GPDs the DGLAP (Dokshitzer-Gribov-Lipatov-Altarelli-Parisi) region where \(x + \xi\) and \(x - \xi\) have the same sign, where the physics resembles the usual parton distribution case, from the ERBL (Efremov-Radyushkin-Brodsky-Lepage) region for which \(-\xi < x < \xi\) and where a quark-antiquark pair is extracted from the meson state. The interpretation of TDAs is more explicit when they are expressed as the overlap of light-cone wave functions for the hadron and the photon. Let us emphasize that all possible spectator configurations have to be summed over in the wave function overlap, including Fock states with additional partons in the hadron and in the photon.

Interesting sum rules may be derived for the meson to photon TDAs. Since the local matrix element describes - up to a charge factor - the photon to neutral meson transition form factor, measurable in \(\gamma\gamma^*\) collisions, we obtain

\[
\int_0^1 dx (Q_u V^u(x, \xi, t) - Q_d V^d(x, \xi, t)) = \sqrt{2} f_\pi F_{\gamma\gamma}(t),
\]

(8)

where \(Q_u = 2/3, Q_d = -1/3\) and \(V^q(x, \xi, t)\) is the TDA related to the operator built from the quark \(q\), see Eq. \[6\]. Current algebra fixes the value of the right hand side at \(t = 0\) since \(F_{\gamma\gamma}(t = 0) = \frac{\sqrt{2}}{8\pi f_\pi}, f_\pi = 138 \text{ MeV}\) \[13\].

In an analogous way one can derive the sum rule for the axial TDAs, related to the axial-vector form-factors measured in the weak decays of mesons \(\pi^+ \rightarrow \ell^+ \nu \gamma\). We get

\[
\int_0^1 dx A(x, \xi, t) = f_\pi F_A(t).
\]

(9)

These two sum rules allow to constrain possible parametrizations of the TDAs. Note, in particular, the \(\xi\) independence of both relations. On the other hand we do not know any sum rule constraining chirally-odd TDAs.

QCD radiative corrections lead as usual to logarithmic scaling violations. The scale dependence of the meson to photon TDAs is governed by evolution equations which are the evolution equations for usual non-singlet GPDs \[\Re\],

\[
\mu^2 \frac{d}{d\mu^2} A(x, \xi, t) = \int_{-1}^1 dx' \left( \frac{1}{\xi} V_{NS}\left( \frac{x}{\xi}, \frac{x'}{\xi} \right) A(x', \xi, t) \right),
\]

(10)
where to the leading order accuracy

\[
V_{NS}(x, x') = \frac{\alpha_s}{4\pi} C_F \left[ \rho(x, x') \left[ \frac{1 + x}{1 + x'} \left( 1 + \frac{2}{x' - x} \right) \right] + \left[ x \rightarrow -x, x' \rightarrow -x' \right] \right] + \rho(x, x') = \theta(x' \geq x) = \theta(x' \leq x) - \theta(x \leq -1),
\]

with \( C_F = (N_c^2 - 1)/(2N_c) \), and the same equations are satisfied by the other leading order TDAs, \( V(x, \xi, t) \) and \( T_i(x, \xi, t), i = 1, 2 \).

3. \( \pi^- \pi^+ \rightarrow l^+l^- \) in the scaling regime

Let us now study the annihilation channel \( \pi^- \pi^+ \rightarrow l^+l^- \) in the kinematical region where \( Q^2, s \rightarrow \infty \) with \( x_B = Q^2/s \) fixed. \( Q^2 \) is the invariant mass of the lepton pair and \( s \) is the center of mass energy squared. The amplitude is the sum of two contributions. The Bremsstrahlung process where the real photon is radiated from a final lepton yields an amplitude proportional to the timelike hadron form factors \( F_\pi(s) \). Such an amplitude is strongly peaked when the photon is collinear to one of the final leptons. It should not interfere much with the process we are mostly interested in which favors the kinematics where the photon is mostly parallel to the \( \pi^+ \).

The \( \pi^- \pi^+ \rightarrow \gamma L \) contribution yields an amplitude which is proportional to the TDAs we have defined with \( \xi \) connected with \( x_B \) by \( \xi = \frac{z^2}{2s} \) in the Bjorken limit. It reads

\[
\mathcal{M}(Q^2, \xi) = \int dx dz \phi(z) M_h(z, x, \xi) A(x, \xi, t),
\]

where the hard amplitude is

\[
M_h(z, x, \xi) = \frac{4\pi^2 \alpha_{em} \alpha_s C_F}{N_c Q} \frac{1}{z \bar{z}} \left( \frac{Q_u}{x - \xi - i\epsilon} + \frac{Q_d}{x + \xi + i\epsilon} \right) \varepsilon \cdot \vec{\Delta},
\]

and \( \phi(z) \) is the meson distribution amplitude, \( \bar{z} = 1 - z \). The scaling law for the amplitude is

\[
\mathcal{M}(Q^2, \xi) \sim \frac{\alpha_s(Q^2)}{Q},
\]

up to the logarithmic corrections due to DA and TDA anomalous dimensions. This behaviour is related to the one of the electromagnetic hadron form factor.

4. Backward VCS

The backward VCS reaction \( eH \rightarrow e'H\gamma \) when the final photon flies approximatively in the direction of the initial hadron receives contributions from two competing subprocesses, namely the Bethe-Heitler process where the final photon is emitted from the lepton line and the hadronic dVCS process where \( \gamma \) is emitted from the hadron. Contrarily to the case of near forward dVCS, the Bethe-Heitler process is strongly suppressed in the backward kinematics. One may thus quite safely ignore its contribution in this study [15].

The hadronic backward VCS process is the spacelike analog of the \( \bar{H}H \rightarrow \gamma L \) process discussed in the previous section. The correspondence between these two amplitudes may be inferred, via crossing, from the analysis of Ref. [11]: at Born level and to leading twist, one obtains the amplitudes for backward dVCS from those of the reaction \( \bar{H}H \rightarrow \gamma L \) by changing the sign of the imaginary part and reversing the beam and virtual photon polarizations. To this accuracy, both processes thus carry exactly the same information on the TDAs. One should however remember that already at the form factor level, there is an experimental difference between timelike and spacelike exclusive quantities which may be the signature of higher twist or higher order corrections [16].

The scaling law for the amplitude is the same as the one written above in Eq. (14).

5. Conclusions

We have defined the new transition distribution amplitudes \( H \rightarrow \gamma \), i.e. which parametrize the matrix elements of light-cone operators between very different initial and final states; this generalizes the concept of GPDs for non-diagonal transitions. In our analysis we assumed that the momentum transfer square \( t \) is small, \( Q^2 \) is large and leads to the scaling. In a real experiment, at finite (and not so large) \( Q^2 \) and when \( -t \) increases from zero to the order of \( Q^2 \), the real photon has to be treated as a part of the hard physics and the process becomes a fixed angle process. Such case may be discussed along the lines of Ref. [1] or analysed with the use of the handbag mechanism of Ref. [17].

The TDAs we introduced are in particular relevant for the reactions involving baryon number exchanges. We have discussed two new cases of factorization in hard exclusive reactions, the soft parts of which are described by the same hadron to photon TDA. Although, for simplicity, our study was concentrated on the mesonic case, we stress that most of our conclusions apply also for the phenomenologically more interesting, but also technically more difficult, baryonic case.

Let us emphasize the main differences between the mesonic and the baryonic cases:

- The relevant matrix element involves three quark fields \( \langle \gamma | u^\alpha(z_1) | z_1; z_0 \rangle u^\beta(z_2) | z_2; z_0 \rangle d^\gamma(z_3 [z_3; z_0]) | p \rangle \mid \bar{x}_L^+ = 0, x_T^+ = 0 \) and consequently it will involve more independent spinor structures than in the meson case.

- The number of independent helicity amplitudes for the process \( p \rightarrow qqq\gamma \) is 16 (there are in this case 25 helicity amplitudes but parity conservation relates amplitudes differing by all the signs of helicities). This allows to predict that there will be 16 independent, leading twist TDAs for the \( p \rightarrow \gamma \) transition. As in the meson case, where only one out of four TDAs actually enters Eq. (12),
less than 16 TDAs are expected to contribute to the amplitude of the processes under study.
- A slight generalization of the scaling law written in Eq. (13) dictates the high $Q^2$ behaviour of the baryonic amplitudes, up to logarithmic corrections

$$\mathcal{M}(Q^2, \xi) \sim Q^{-2n_v+3},$$

(15)

where $n_v$ is the number of valence partons in the hadron ($n_v = 3$ for the proton).
- The QCD evolution equations for the TDAs in the baryonic case are more involved since the radiated gluon may be coupled to each pair of exchanged quarks and the evolution kernel depends on the direction of these quark momenta. New evolution equations may be written in a way which takes care of the different sectors in longitudinal momentum fractions of the three exchanged quarks.

The framework which we present in the present paper is very different from the handbag dominance model which has been proposed to describe the annihilation reaction $p\bar{p} \to \gamma\gamma$. Such a model, based on an analogy with the reaction $\gamma^* \gamma \to \pi^+ \pi^-$ at small energies, predicts a different scaling behaviour at large $Q^2$ and a different helicity structure. Although these two approaches deal with different kinematical domains (the present one studies the forward and backward cases, those of Ref. 17 concentrates on fixed large angle kinematics) which are well distinct at asymptotic energies, actual experimental data at moderate values of $Q^2$ and $s$ may not well separate these two regions. It should be important to investigate in detail the phenomenological differences of these two approaches. Experimental tests of our picture should be feasible in the near future. Already now experimental data exist on backward VCS at JLab up to $Q^2 = 1$ GeV$^2$ [10]. Further experiments on backward VCS are planned with higher energy and rates at JLab, Hermes and COMPASS experiments. The Panda and PAX experiment with the proposed $1.5 - 15$ GeV high-luminosity antiproton storage ring (HESR) at GSI [9] intend to study the proton antiproton annihilation reaction. Let us finally note that $p \to \pi$ TDAs may also be defined in an analogous way [19], allowing a similar description of reactions such as

$$p\bar{p} \to \gamma^* \pi \quad \text{or} \quad \gamma^* p \to p\pi.$$  

Again these processes are likely to be measurable in forthcoming experiments at GSI, JLab and HERMES.
