(Dated: May 5, 2014)

We carried out specific-heat and ac-susceptibility experiments under hydrostatic pressure to investigate the interplay of spin-density-wave antiferromagnetism (A) and superconductivity (S) in single-crystalline AS-type CeCu$_2$Si$_2$. We find evidence for a line of magnetic-field- and pressure-tuned quantum critical points in the normal state in the zero-temperature magnetic field – pressure plane. Our analysis suggests an extension of this line into the superconducting state and corroborates the close connection of the underlying mechanisms leading to the formation of the antiferromagnetic and the superconducting states in AS-type CeCu$_2$Si$_2$.

The discovery of superconductivity in heavy-fermion (HF) [1], organic [2], cuprate [3], and most recently in pnictide materials [4] changed our understanding of superconductivity completely. Despite fundamental differences between these families, the proximity of a magnetic ground-state instability to the superconducting (SC) phase is a common theme in all of the SC systems. In pnictide, organic, and some HF superconductors itinerant (spin-density-wave, SDW, type) antiferromagnetism seems to be closely related to the formation of the SC phase, suggesting a magnetically mediated SC pairing mechanism. The Néel temperature, $T_N$, can generally be tuned as function of some external parameter, such as doping or pressure. Typically, superconductivity develops in the vicinity of the point where $T_N$ disappears as a function of the external parameter [e.g. [2,3]]. The normal state transport and thermodynamic properties close to that point often disclose a region of non-Fermi-liquid (NFL) behavior hinting at the presence of a (hidden) quantum critical point (QCP) [4]. In the cuprates and iron-pnictides the SC upper-critical-field ($B_{c2}^0$) is generally accessible only by pulsed magnetic-fields putting strong restrictions on the available experimental probes and their accuracy. In contrast to these classes of materials, in HF superconductors $B_{c2}^0$ is moderate and the SC state can be easily suppressed using standard laboratory equipment. This makes the HF materials perfect model systems for an in-depth investigation of the interplay of magnetism and superconductivity and a testbed for the theoretical models developed.

CeCu$_2$Si$_2$, the first discovered HF superconductor [1], is ideally suited to study the interplay of SDW antiferromagnetism and superconductivity. The ground state of CeCu$_2$Si$_2$ depends strongly on the exact stoichiometry. It ranges from (i) antiferromagnetism (A-type), coexisting in a small parameter range with low-$T_c$ superconductivity, via (ii) antiferromagnetism which is replaced by superconductivity on lowering temperature, or recovered when superconductivity is suppressed by a sufficiently large magnetic field (AS-type), to (iii) solely superconductivity (S-type). The antiferromagnetic (AF) order in A-type CeCu$_2$Si$_2$ was shown to be an incommensurate SDW, with a very small ordered moment ($\mu \approx 0.1 \mu_B$) [5]. In AS-type CeCu$_2$Si$_2$ the AF and SC ordering temperatures are comparable. Resistivity and specific-heat results obtained in the field-driven low-$T$ normal state of S-type CeCu$_2$Si$_2$ revealed NFL phenomena, highly consistent with a three dimensional (3D) SDW QCP [5]. The SC phase in CeCu$_2$Si$_2$ is rather robust against external pressure covering more than 5 GPa. Introduction of disorder by Ge-doping on the Si-site revealed the presence of two distinct SC domes. The SC state at low pressures is supposed to be mediated by AF spin fluctuations, while at high pressures superconductivity is suggested to be mediated by valence fluctuations [10]. An analysis of thermodynamic data evidences the existence of different SC order parameters in the two distinct SC phases [11].

In this Letter we will substantiate the close link between superconductivity and antiferromagnetism in the low-$p$ region in AS-type CeCu$_2$Si$_2$. Furthermore, we provide evidence for the existence of a line of magnetic-field- and pressure-tuned QCP’s which extends into the SC region of the magnetic field – pressure phase diagram.

Heat-capacity and ac-susceptibility experiments under hydrostatic pressure have been performed on a single-crystalline sample of AS-type CeCu$_2$Si$_2$ (0.26 K $\leq T \leq 7$ K, $B_{c2} \leq 8$ T). The resolution of the ac-susceptibility measurements only allows for observing the SC transition, the AF transition anomaly cannot be resolved. The measurements were carried out in a single-layer CuBe piston-cylinder type pressure cell (for details see [11]).

Figure [1] displays the electronic contribution to the specific heat as $C_{el}(T)/T$ at selected pressures. At atmospheric pressure AS-type CeCu$_2$Si$_2$ undergoes two consecutive phase transitions below $T = 1$ K upon decreasing temperature, the first one at $T_N \approx 0.69$ K, to an incommensurate AF SDW type of order [8] and the second one at a slightly lower temperature, marking the onset of superconductivity at $T_c \approx 0.46$ K. The highly enhanced value of the electronic specific-heat coefficient at low temperatures, $C_{el}/T \approx 0.73$ J/(molK$^2$) at $T = 0.9$ K, indicates the HF character. A Kondo tem-
temperature of $T_K \approx 13$ K can be determined by analyzing the entropy in the frame of the single-impurity Kondo model \[12\]. At $T_N$, the entropy reaches a value of only $S_{el}(T_N) \approx 0.11R\ln 2$, as anticipated from the small ordered moment of $\mu_{ord} \approx 0.1 \mu_B$ per Ce atom detected by neutron-diffraction experiments in the AF state \[8\].

Application of a small hydrostatic pressure leads to a rapid shift of $T_N(p)$ to lower temperatures with an initial slope of $dT_N/dp \mid_{p=0} \approx -1.17$ K/GPa, while $T_c(p)$ at first strongly increases ($dT_c/dp \mid_{p=0} \approx 2.33$ K/GPa). In contrast to hydrostatic pressure, a magnetic field suppresses both $T_N$ and $T_c$. $T_c$ being much more sensitive to the magnetic field than $T_N$. As a consequence, at 0 GPa and 0.04 GPa the two transition anomalies in specific heat become more separated in an external magnetic field. At ambient pressure no indication for a SC transition is present in the data at $B = 1$ T anymore in our accessible temperature range ($T > 0.27$ K), while at 0.04 GPa the anomaly at $T_c$ is visible in $B = 1$ T, but absent in 2 T indicating an enhanced SC upper-critical field, $B_{c2}^{\text{up}}$, compared with zero pressure. A further pressure increase to only $p = 0.06$ GPa is sufficient to shift the two phase transitions very close to each other resulting in a single broadened anomaly in $C_{el}(T)/T$. In a closer analysis the transition temperatures $T_N \approx 0.62$ K and $T_c \approx 0.60$ K can be extracted. Upon increasing the magnetic field the anomaly in $C_{el}(T)$ further broadens reflecting the different dependencies of $T_N$ and $T_c$ on the magnetic field. While for $B < 2$ T the $\chi_{ac}(T)$ data confirm the presence of the SC transition, at 2 T no diamagnetic signal is observed anymore proving that the anomaly observed in specific heat corresponds only to the AF transition and superconductivity is already suppressed. At a slightly larger pressure, $p = 0.09$ GPa, a single sharp anomaly in specific heat at $B = 0$ signals the transition to the SC state. $\chi_{ac}(T)$ experiments prove the presence of superconductivity up to $B = 1.5$ T. We find no hint at a magnetic transition below $T_c$. At 2 T $\chi_{ac}(T)$ does not show any diamagnetic signal anymore, but $C_{el}(T)/T$ exhibits a broad anomaly. Therefore, we identify this anomaly with the transition into the AF state. At higher pressures (not shown), no indication for a magnetic transition is observed in the field-induced normal state anymore. Especially, no signature of an AF phase transition inside the SC state is found at any magnetic field and pressure. Our results clearly indicate that once $T_c(p)$ for a fixed $B$ becomes larger than $T_N(p)$ the presence of the AF phase transition cannot be detected anymore. This strongly suggests the absence of any long-range magnetic ordering inside the SC phase. We therefore conclude that the antiferromagnetically ordered state in AS-type CeCu$_2$Si$_2$ is expelled once superconductivity has been established.

The deduced low-pressure $T - p$ phase diagram of AS-type CeCu$_2$Si$_2$ is presented in Fig. 2. At zero magnetic field $T_c(p)$ exhibits a weak maximum around $p_{T_c,\text{max}} \approx 0.4$ GPa. Although, we cannot follow $T_N(p)$ inside the SC state, we can extrapolate $T_N(p)$ from the normal into the SC state. We follow the predictions of the spin-fluctuation theory for a 3D SDW QCP and use $T_N(p) \propto (p - p_c)^{2/3}$ to extrapolate $T_N(p)$ \[13\]. By our analysis, we obtain a critical pressure, $p_c \approx 0.39$ GPa, which nearly coincides with the position of the maximum in $T_c(p)$. We have utilized the same approach to extrapolate the $T_N(p, B = \text{const.})$ data taken in magnetic fields ($B = 0.5$ T, 1 T, and 2 T). With increasing magnetic field the critical pressure $p_c(B)$ and the position of the maximum in $T_c(p, B = \text{const.})$, $p_{T_c,\text{max}}(B)$, also coincide and shift to lower pressures. The tight correlation of $p_c(B)$ and $p_{T_c,\text{max}}(B)$ thus suggests a strong link between the underlying mechanisms leading to the formation of the two ordered phases in CeCu$_2$Si$_2$.

As pointed out before, we do not detect any magnetic phase-transition anomaly inside the SC state. Clear evidence for microscopic coexistence of magnetism and (low $T_c$) superconductivity has only been found at negative
chemical pressures \[14\]. Thus, we speculate that despite the fact that we cannot identify a magnetic phase transition or a QCP inside the SC state their *halo* is present. For AF spin-fluctuation mediated superconductivity the maximum of the SC dome is expected at the critical point where magnetism is completely suppressed \[13,16\]. This is in agreement with our findings for \(\text{AS-type CeCu}_2\text{Si}_2\). However, in zero magnetic field \(T_c(p)\) only exhibits a weak maximum at the critical pressure, \(p_c \approx 0.39\) GPa, in contrast to the pronounced SC dome typically observed in HF superconductors, e.g. \[8\]. The almost pressure independent behavior of \(T_c(p)\) in \(\text{AS-type CeCu}_2\text{Si}_2\) might be related to the influence of the additional pairing mechanism provided by the valence fluctuations present at higher pressures \[10,11,17\] and, thus, indicating that already in this relatively low-pressure region of the phase diagram the two SC pairing mechanisms have to be considered.

Application of both, magnetic field \(B \parallel c\) and pressure, leads to a gradual suppression of the AF order in \(\text{AS-type CeCu}_2\text{Si}_2\). While, as already discussed above, for a fixed magnetic field the \(T_N(p)\) curve cannot be followed inside the SC phase anymore, at a constant pressure \(T_N\) can be continuously suppressed to zero temperature by increasing the magnetic field suggesting the presence of field-induced QCP’s. The experimental data, \(T_N(B, p = \text{const.})\), are well described by the empirical formula \(B_n(T) = B_n^0[1 - (T/T_n^0)^n]\), where \(T_n^0\) is the Néel temperature at \(B = 0\), \(B_n^0 = B(T_N = 0)\), and \(n\) is a fitting parameter. \(n\) was determined once at ambient pressure \((n = 3.9)\) and then kept constant for all other pressures. The results of the fits are indicated by the white lines in Fig. 3. The critical points in the \(p - B\) plane at \(T = 0\), \(B_n^0(p)\), follow a straight line. This is indicated in Fig. 3 by the dashed line. At ambient pressure \(B_n^0(p = 0) \approx 4\) T. An increase of pressure leads to a gradual decrease of \(B_n^0(p)\) for \(B \parallel c\) (for \(B \parallel a\), \(B_n^0(p)\) shows initially only a weak pressure dependence \[18\]). At about \(p = 0.18\) GPa and \(B = 2.1\) T the line of critical points hits the SC phase boundary (solid line in Fig. 3), right at the maximum of the upper critical field, \(B_n^0(p)\), suggesting again a close connection of antiferromagnetism and superconductivity in \(\text{AS-type CeCu}_2\text{Si}_2\). The estimated critical points inside the SC phase \([T_N(p, B = \text{const.}) \rightarrow 0, \text{see above}]\), which coincide rather well with the position of the maximum in \(T_c(p)\), lie on the same straight line (dotted line in Fig. 3) as the critical points in the normal state. We note that the HF compound CeRhIn\(_5\) exhibits a similar \(T - p\) phase diagram at \(B = 0\) \[7\]. However, in CeRhIn\(_5\) the AF state is robust against the application of a magnetic field, even field-induced magnetism extending into the SC state is observed \[19,20\]. This behavior in magnetic field is in strong contrast to the observations in \(\text{CeCu}_2\text{Si}_2\).

To search for further evidence for the presence of a line of field-induced QCP’s in the zero temperature \(p - B\) plane we analyzed \(C_{el}(T)\) in the normal state. In the proximity of a QCP strong deviations from Landau-Fermi-liquid (LFL) behavior are expected. Figure 4 shows the pressure evolution of \(C_{el}(T)/T\) at \(B = 6\) T on a \(\sqrt{T}\) temperature scale. At ambient pressure, \(C_{el}(T)/T\) increases as \(\gamma_0 - a\sqrt{T}\) on lowering the temperature \(T \lesssim \)}
