We investigate the Landau-Zener tunneling (LZT) of a self-interacting two-level system in which the coupling between the levels is nonreciprocal. In such a non-Hermitian system, when the energy bias between two levels is adjusted very slowly, i.e., in the adiabatic limit, we find that a quantum state can still closely follow the eigenstate solution until it encounters the exceptional points (EPs) at which two eigenvalues and their corresponding eigenvectors coalesce. In the absence of the nonlinear self-interaction, we can obtain explicit expressions for the eigenvectors and eigenvalues and analytically derive the adiabatic LZT probability from invariants at EPs.

In the presence of the nonlinear interaction, the dynamics of the adiabatic evolutions are explicitly demonstrated with the help of classical trajectories in the plane of the two canonical variables of the corresponding classical Josephson Hamiltonian. We show that the adiabatic tunneling probabilities can be precisely predicted by the classical action at EPs in the weak nonreciprocal regime. In a certain region of strong nonreciprocity, we find that interestingly, the nonlinear interaction effects can be completely suppressed so that the adiabatic tunneling probabilities are identical to their linear counterparts. We also obtain a phase diagram for large ranges of nonreciprocity and nonlinear interaction parameters to explicitly demonstrate where the adiabaticity can break down, i.e., the emergence of the nonzero tunneling probabilities even in adiabatic limit.

I. INTRODUCTION

Landau-Zener tunneling (LZT) is a well-known phenomenon discussed in the quantum mechanics textbooks that describes a system that goes from one side of an avoided level crossing to the other side at a certain sweeping rate [1, 2]. The LZT model has many important applications in various physical systems demonstrated by recent progress in experiments, for example in superconducting qubits [3–5], nitrogen-vacancy centers [6], quantum dots [7, 8], waveguide arrays [9], and Bose-Einstein condensates [10–27], to name only a few.

The LZT model has many extensions by taking diverse physical conditions into account, such as in multilevel systems [28–36], in a nonlinear interacting system with level energies depending on the occupation of the levels [10–12], and in a time-dependent sweeping scheme [37, 38]. All of the above studies focus on Hermitian systems that are assumed to be conservative, obey time-reversal symmetry, and obviously exhibit real-valued eigenvalues. However, in many situations, nonconservative elements arise in various forms, so that non-Hermitian physics have recently attracted considerable attention [39–47]. Recently, the extensions of the LZT to non-Hermitian systems have also been studied by considering level decay and dephasing effect [48–51].

In the present paper, we attempt to investigate the LZT in a nonreciprocal self-interacting two-level system, in which the non-Hermiticity is induced by the nonreciprocal coupling between the levels in contrast to the level decay and dephasing effects [49–51]. The nonreciprocity of state transitions can be harnessed to engineer an effective non-Hermitian Hamiltonian [46, 47, 52, 53] that maintains the time-reversal symmetry but violates the parity symmetry. The Bogoliubov-de Gennes equation that describes the dynamics of noncondensed atoms in a Bose-Einstein condensate [54–56] has this type of symmetry. This approach has been also used to realize a non-Hermitian Su-Schrieffer-Heeger model with asymmetric intra-unit-cell hopping amplitudes [57]. Nonreciprocity plays an important role not only in fundamental studies such as investigations of topological photonics [58, 59] and chiral quantum optics [60] but also in applied research such as optical communication and information processing [61–64]. Recently, tunable nonreciprocal hopping has been realized in cold atoms in optical lattices [46, 65, 66] and in synthetic momentum lattices [67].

Additionally, quantum adiabatic evolution is an important concept in quantum mechanics [68, 69] that has been widely applied in the preparation and control of quantum states [70–73]. According to the adiabatic theorem of quantum mechanics, an initial nondegenerate eigenstate remains an instantaneous eigenstate if a Hamiltonian is changed sufficiently slowly compared to the level spacings. It predicts a zero quantum transition between the energy levels in the adiabatic limit of the Hamiltonian’s change. Adiabatic theory has been extended to quantum systems with nonlinear interactions [16, 74], showing many applications [75–77]. Recently, in the context of non-Hermitian systems, several studies on possible new phenomena of adiabatic evolution have been carried out [73, 78–80]. In this paper, we address this issue by investigating an extended LZT model with nonreciprocal coupling, emphasizing the impact of the interplay of nonreciprocity and nonlinear interactions on the adiabatic evolution. Interestingly, we find that, the emergence of exceptional point (EP) singularities dramatically alters the tunneling process, leading to the breakdown of adiabaticity, i.e., the emergence of nonzero tunneling probabilities even in the adiabatic limit of the energy bias change. Our results are of significance in the fields of quantum optics and quantum transport. They also have potential application in quantum in-

II. PHYSICAL MODEL AND JOSEPHSON HAMILTONIAN

A. Nonreciprocal Landau-Zener model

We consider a nonreciprocal Landau-Zener model as illustrated by Fig. 1, whose Hamiltonian takes the following form:

\[ H(\gamma) = \left( \begin{array}{c} \frac{\gamma}{2} + c|a|^2 \\ \frac{\gamma}{2}(1 - \delta) \end{array} \right) \left( \begin{array}{c} a \\ b \end{array} \right), \tag{1} \]

where \((a, b)\) is the two-mode wavefunction, \(v\) is the constant for the hopping between the two levels, \(\gamma\) is the level bias, \(c\) denotes the nonlinear self-interaction parameter indicating the population-dependent level energy, and \(\delta > 0\) is the nonreciprocity parameter that results in non-Hermiticity. Since the Hamiltonian can be scaled by dividing by \(v\), for convenience, we can set \(v = 1\) as the energy unit hereafter.

The dimensionless Schrödinger equation is

\[ i\frac{d}{dt} \begin{pmatrix} a \\ b \end{pmatrix} = H(\gamma) \begin{pmatrix} a \\ b \end{pmatrix}. \]

As in the standard Landau-Zener model, the parameter of the level bias \(\gamma\) changes linearly with time as \(\gamma = \alpha t\). The constant rate \(\alpha\) is the sweeping rate.

As illustrated in Fig. 1, we assume that the system is initially found in the lower (or upper) energy level, i.e., \((a(t \rightarrow -\infty), b(t \rightarrow -\infty))^T = (1, 0)^T\) (or \((a(t \rightarrow -\infty), b(t \rightarrow -\infty))^T = (0, 1)^T\)). Since Hamiltonian (1) is non-Hermitian, the distinct feature is the appearance of complex eigenvalues. Thus, the time evolution of such a non-Hermitian system is no longer unitary and the total population (i.e., \(N = n_a^2 + n_b^2\) with \(n_a = |a|^2\) and \(n_b = |b|^2\)) is not a conserved quantity. Thus, the transition probability from the lower to the upper or from the upper to the lower level can be denoted by the following:

\[ P_{LU} \equiv \frac{n_a^2(t \rightarrow +\infty)}{N(t \rightarrow +\infty)}, \quad P_{UL} \equiv \frac{n_b^2(t \rightarrow +\infty)}{N(t \rightarrow +\infty)}. \tag{2} \]

In the absence of nonreciprocity \(\delta\) and nonlinear interaction \(c\), Hamiltonian (1) degenerates into a standard linear LZT two-level system. The probability of the transition between the two energy levels is represented by the formula \([1, 2]\)

\[ P_{UL} = \exp(-\frac{\alpha t}{2\gamma}). \]

In the adiabatic limit, that is, as the sweeping rate \(\alpha\) tends to zero, the transition probability tends to zero, indicating that an initial quantum state can closely follow the instantaneous eigenstate and remain in the adiabatic (upper or lower) energy level.

The presence of a nonlinear interaction \(c\) can dramatically alter the tunneling dynamics \([10-27]\). The most striking feature is the breakdown of adiabaticity for a large nonlinear parameter, which is intimately linked to the hysteresis phenomena and the existence of the swallowtail loops in the adiabatic energy levels \([10, 12, 13, 16, 81]\). The underlying mechanism has been revealed by investigating an equivalent classical Josephson Hamiltonian, in which the nonzero adiabatic tunneling probability can be explained as a jump in the classical canonical action \([12, 16]\).

The presence of nonreciprocity parameter \(\delta\) in Hamiltonian (1) can result in nonreciprocal state transitions between two levels. In contrast to the \(PT\)-conserved non-Hermitian systems \([39]\), this non-Hermitian system maintains the time-reversal symmetry but violates the parity symmetry.

In the present paper, we focus on the adiabaticity in the nonreciprocal LZT by investigating the tunneling probabilities in the adiabatic limit of the energy bias change, i.e., \(P_{UL}^{\text{adi}} = \lim_{\alpha \to 0} P_{UL}\) and \(P_{UL}^{\text{adi}} = \lim_{\alpha \to 0} P_{UL}\). According to the adiabatic theorem, when adiabaticity is maintained, the adiabatic tunneling probabilities should be zero. Nevertheless, the emergence of EPs can cause the breakdown of the adiabaticity and lead to nonzero adiabatic tunneling probability. Our theoretical analysis is facilitated by the following Lagrangian representation that help us to derive a classical Josephson Hamiltonian.

B. Lagrangian and Classical Josephson Hamiltonian

The Schrödinger equation that governs the nonreciprocal LZT can be derived from the time-dependent variational principle, where the action is defined as the time integral of a
We note that the above classical Hamiltonian \((\gamma = \alpha t) = (a(t), b(t))^T\). Here, the Lagrangian is found to be as follows:

\[
L = \left\{ i\hbar \frac{d}{dt}\psi \right\} - (\psi | \sigma H_0 | \psi) - \frac{c}{4} (\psi | \sigma (\sigma_3 \rho \sigma_3 + \rho) | \psi),
\]

where \(\sigma = \left( \begin{array}{cc} 1 - \delta & 0 \\ 0 & 1 \end{array} \right)\). 

The Hamiltonian is then cast into the following form:

\[
L = \left( (1 - \delta n_a n_a - \delta n_b n_b) - v(1 - \delta) n_a n_b \cos (\theta_b - \theta_a) - \frac{c}{2} (1 - \delta) n_a \right). 
\]

One can naturally obtain a classical Hamiltonian from the Lagrangian (4) using the relationship \(H' = \langle \psi | i\hbar \frac{\partial}{\partial \psi} | \psi \rangle - L\).

We then introduce the following four canonical variables,

\[
\begin{align*}
\theta_+ &= \theta_1 + \theta_2, \\
\theta_- &= \theta_1 - \theta_2, \\
\zeta_+ &= n_a^2 + \frac{1}{1 - \delta} n_b^2, \\
\zeta_- &= n_a^2 - \frac{1}{1 - \delta} n_b^2.
\end{align*}
\]

In terms of \(\theta_\pm, \zeta_\pm, \) and \(\zeta_-, \) the classical Hamiltonian can be expressed as follows:

\[
H' = \gamma \zeta_+ + v \sqrt{(1 - \delta)} \left( \zeta_+ - \zeta_- \right) \cos \theta_- + \frac{c(2 - \delta)}{4} \left( \zeta_+^2 + \zeta_-^2 \right) + \frac{c}{2} \gamma \zeta_-.
\]

We note that the above classical Hamiltonian (6) can be reduced to either the famous Josephson Hamiltonian [82–84] when \(\delta = c = 0\), or to its nonlinear extension when \(\delta = 0\) and \(c \neq 0\) [12, 77].

From the Hamilton’s canonical equations \(\dot{\theta}_+ = -\partial H'/\partial \zeta_-, \end{equation} \(\dot{\theta}_- = -\partial H'/\partial \zeta_+, \) \(\dot{\zeta}_+ = -\partial H'/\partial \theta_-\), and \(\dot{\zeta}_- = -\partial H'/\partial \theta_+\), one can readily obtain the following equations of motion.

\[
\begin{align*}
\dot{\theta}_+ &= \frac{c}{2} \delta \zeta_- - \frac{c}{2} (2 - \delta) \theta_- - \frac{(1 - \delta)}{\sqrt{1 - \delta}} \frac{\cos \theta_-}{\left( \sqrt{1 - \delta} \left( \zeta_+ - \zeta_- \right) \right)}, \\
\dot{\theta}_- &= -\gamma \sqrt{1 - \delta} \left( \zeta_+ - \zeta_- \right) \sin \theta_-, \\
\dot{\zeta}_+ &= -\gamma \sqrt{1 - \delta} \left( \zeta_+ - \zeta_- \right) \cos \theta_-, \\
\dot{\zeta}_- &= -\gamma \sqrt{1 - \delta} \left( \zeta_+ - \zeta_- \right) \cos \theta_-.
\end{align*}
\]

Clearly, \(\zeta_-\) is an invariant that is determined by the initial state. Nevertheless, when the parameters change adiabatically, an initial state may encounter EPs; in this situation, we find that the singularity of the EPs may cause a sudden change in the invariant as will be shown in the next section.

In terms of \(\zeta_+\) and \(\zeta_-\), the total population \(\mathcal{N} = n_a^2 + n_b^2 = \frac{2}{\sqrt{1 - \delta}} \zeta_+ + \frac{2}{\sqrt{1 - \delta}} \zeta_-\). From Eq. (7), we can also deduce the following differential equation:

\[
\mathcal{N} = -\frac{\delta v}{2} \sqrt{(1 - \delta)} \left( \zeta_+^2 - \zeta_-^2 \right) \sin \theta_-.
\]

III. NONRECIPROCAL LZT IN THE ABSENCE OF NONLINEAR INTERACTIONS \((c = 0)\)

A. Energy level and nonreciprocal LZT

When \(c = 0\), the eigenvalues and eigenstates of Hamiltonian (1) can be readily obtained. The adiabatic levels are given by the following:

\[
\varepsilon_\pm = \pm \frac{1}{2} \sqrt{\gamma^2 + \nu^2 (1 - \delta)}.
\]

The corresponding eigenstates are given by the following:

\[
|\psi_-\rangle = C_1 \left( \frac{\gamma - \sqrt{\gamma^2 + \nu^2 (1 - \delta)}}{\nu (1 - \delta)}, 0 \right)^T, \]

\[
|\psi_+\rangle = C_2 \left( \frac{\gamma + \sqrt{\gamma^2 + \nu^2 (1 - \delta)}}{\nu (1 - \delta)}, 0 \right)^T.
\]

Here, \(C_1\) and \(C_2\) are normalization coefficients.

EPs at which two eigenvalues and their corresponding eigenvectors coalesce and become degenerate are a distinct
feature in non-Hermitian quantum systems. For nonreciprocity parameter \( \delta \geq 1 \), the conditions for EPs can be easily obtained, that is, \( \gamma_{EP} = \pm \sqrt{\delta - 1} \). The eigenvalues are real when \( |\gamma| > \gamma_{EP} \); otherwise, they are imaginary. The corresponding eigenvectors at EPs coalesce as described by the following:

\[
|\psi_{EP}\rangle_{\pm} = \left( \mp \frac{1}{\sqrt{\delta}}, \frac{\sqrt{\delta - 1}}{\sqrt{\delta}} \right)^T,
\]

where the sign \( \mp \) is for the \( \pm \gamma_{EP} \) EPs, respectively. For nonreciprocity parameter \( \delta < 1 \), there are no EPs, and the eigenvalues are always real.

The level bias \( \gamma \)-dependence of the energy levels is shown in Fig. 2. When \( \delta < 1 \), the imaginary parts of the eigenvalues are always zero, and the real parts of the eigenvalues show an avoided level crossing at \( \gamma = 0 \). For \( \delta = 1 \), the eigenvalues show a level crossing at \( \gamma = 0 \). For \( \delta > 1 \), with increasing \( \gamma \), EPs occur at \( \gamma_{EP} \), and the corresponding eigenvalues coalesce. Between two EPs, the real parts of the eigenvalues are zero, whereas the imaginary parts of the eigenvalues are nonzero.

Note that the corresponding eigenstates are not orthogonal to each other. For \( \gamma \rightarrow \pm \infty \), we have \( e \rightarrow \pm |\gamma|/2 \). For instance, for the lower level, we have \( (a, b)^T \rightarrow (1, 0)^T \) at \( \gamma \rightarrow -\infty \) and \( (a, b)^T \rightarrow (0, 1)^T \) at \( \gamma \rightarrow +\infty \).

We now focus on the nonreciprocal LZT. The numerical results of the tunneling probability for different sweeping rates \( \alpha \) and nonreciprocity parameters \( \delta \) are shown in Fig. 3. Figures 3(a) and (b) show the tunneling probabilities \( P_{LU} \) and \( P_{UL} \), respectively, as a function of the sweeping rate \( \alpha \) for different nonreciprocity parameters \( \delta = 0, 0.5, 1, \) and 3. For \( \delta = 0 \), both the tunneling probabilities \( P_{LU} \) and \( P_{UL} \) are consistent with the standard formula of the LZT probability. For \( \delta \neq 0 \), nonreciprocity greatly changes the LZT, resulting in breaking of the symmetry in the tunneling between the two levels, i.e., \( P_{LU} \neq P_{UL} \). For \( \delta = 0.5 \), the tunneling probabilities \( P_{LU} \) and \( P_{UL} \) are both exponentially small as the value of \( \alpha \) approaches zero. For \( \delta = 1 \), with the increase in \( \alpha \), the tunneling probability \( P_{LU} \) remains 1, whereas the tunneling probability \( P_{UL} \) is exponentially small as the value of \( \alpha \) approaches zero. For \( \delta = 3 \), the tunneling probabilities \( P_{LU} \) and \( P_{UL} \) both decrease as \( \alpha \) decreases. For subcritical values of the nonreciprocity parameter \( \delta < 1 \), the tunneling probability still exponentially vanishes with \( \alpha \). Most strikingly, the tunneling probabilities \( P_{LU} \) and \( P_{UL} \) for \( \delta > 1 \) are both zero in the adiabatic limit \( \alpha \rightarrow 0 \), while they are zero for \( \delta < 1 \). This shows that \( \delta = 1 \) is the critical point for the adiabatic time evolution.

Figures 3(c) and (d) more clearly depict the tunneling probabilities \( P_{LU} \) and \( P_{UL} \), respectively, as a function of the nonreciprocity parameter \( \delta \) for different sweeping rates \( \alpha = 0.01, 2, \) and 10. In the adiabatic limit, i.e., \( \alpha = 0.01 \), the tunneling probabilities \( P_{LU} \) and \( P_{UL} \) both remain zero when \( \delta < 1 \). At \( \delta = 1 \), \( P_{LU} \) quickly reaches 1, whereas \( P_{UL} \) remains 0. For \( \delta > 1 \), with increasing \( \delta \), \( P_{LU} \) decreases as a function with the form of \( 1/\delta \), and \( P_{UL} \) increases as a function with the form of \( (\delta - 1)/\delta \). In the nonadiabatic cases, i.e., \( \alpha = 2, 10 \), as \( \delta \) increases from 0 to 1, \( P_{LU} \) increases continuously. When \( \delta = 1 \), \( P_{LU} \) reaches the saturation value of 1 regardless of \( \alpha \); then, as \( \delta \) continues to increase, \( P_{UL} \) keeps decreasing. When \( \delta \) reaches a sufficiently large value, \( P_{LU} \) decreases to 0.

From the above results, we find that even in the adiabatic limit \( \alpha \rightarrow 0 \), the tunneling probability can take nonzero values, depending solely on the nonreciprocity parameter in the forms of \( 1/\delta \) and \( (\delta - 1)/\delta \), as indicated by the cyan curves in Figs. 3(c) and 3(d).

**B. Nonreciprocity breaks adiabaticity**

To gain insight into the adiabaticity in nonreciprocal LZT, we calculate the dynamical energy in the temporal evolution \([10, 27]\). For the wavefunction \( \psi(\gamma = \alpha t) = (a(t), b(t))^T \) of the Schrödinger equation with the Hamiltonian (1), the dynamical energy can be obtained by calculating the energy expectation values of the dynamic states:

\[
\epsilon_{Dyn}(\gamma) = \frac{\langle \psi(\gamma = \alpha t)|H(\gamma)|\psi(\gamma = \alpha t) \rangle}{\langle \psi(\gamma = \alpha t)|\psi(\gamma = \alpha t) \rangle}.
\]

According to the adiabatic theorem, when adiabaticity is maintained, the dynamical energy level at a very small sweeping rate will perfectly follow the adiabatic energy level. A situation where the dynamical energy cannot follow the adiabatic level even for a very small sweeping rate indicates the
breakdown of adiabaticity and the system manifests a nonzero adiabatic tunneling probability [10, 27]. A comparison of the dynamical levels $\varepsilon_{\text{dyn}}$ and the adiabatic levels $\varepsilon_{\text{Eigen}}$ is shown in Fig. 4. Figures 4(a) and (b) show the results for $\delta = 0.5$, and (c) and (d) show those for $\delta = 1$. The initial state is prepared in the lower level (i.e., $(a, b)^T = (1, 0)^T$) for Figs. 4(a) and (c) and in the upper level (i.e., $(a, b)^T = (0, 1)^T$) for Figs. 4(b) and (d). The results are shown in Fig. 4 for the adiabatic limit with $\alpha = 0.01$. In Figs. 4(a) and (b), we observe an excellent match between the dynamical levels and the adiabatic levels, which is similar to the reciprocal case of $\delta = 0$ [10]. Our further calculations demonstrate that for $\delta < 1$, the quantum state can closely follow the corresponding eigenstates in the adiabatic evolution, indicating that adiabaticity is maintained.

At the critical value of $\delta = 1$, the upper level and lower level cross at $\gamma = 0$. We calculate the dynamical energy levels, shown in Figs. 4 (c) and (d). The results show that the initial state starting from both the upper level and lower level can finally evolve into the upper level. When $\delta = 1$, the adiabatic levels of Hamiltonian (1) are given by $\varepsilon_{a,b} = \pm \gamma$, and the corresponding adiabatic states are given by $|e\rangle_{s=1} = (-\sqrt{2} / \gamma, 1)^T$ and $|e\rangle_{s=1} = (1, 0)^T$. For $\gamma \to 0$, both eigenvalues $\varepsilon_{a,b} \to 0$ and the normalized eigenvectors coalesce as $|e\rangle_{s=1} \to (1, 0)^T$, indicating the appearance of an EP. Because the term of $\sqrt{1 - \delta / 2}$ in Hamiltonian (1) vanishes when $\delta = 1$, the Schrödinger equation can be solved analytically as $\psi(t) = a_0 e^{-\frac{\alpha t}{2}} - \frac{(1+\gamma)}{\sqrt{\alpha}} e^{-\frac{\gamma t}{2}} \sigma_0 \sigma_0 \sigma_0$, and $b(t) = b_0 e^{\frac{\gamma t}{2}}$, where the symbol erfi represents the imaginary error function, and coefficient vector $(a_0, b_0)^T$ is given by the normalized eigenvector $(1, 0)^T$ at EP. Then, we have $a(t) = e^{\frac{-\gamma t}{2}}$ and $b(t) = 0$ for $t > 0$. Thus, the normalized wavefunction is $(\tilde{a}(t), \tilde{b}(t))^T = (1, 0)^T$. This indicates that the initial state starting from either the upper level or the lower level will finally evolve into the upper level.

For $\delta > 1$, EPs occur at $\gamma = \pm \gamma_{\text{EP}}$. Therefore, when $\gamma$ changes from $-\infty$ to $+\infty$, the system will pass through the EPs; here, the adiabaticity may break. A comparison of the dynamical levels $\varepsilon_{\text{dyn}}$ and the adiabatic levels $\varepsilon_{\text{Eigen}}$ for $\delta = 3$ is shown in Fig. 5. Figures 5(a) and (b) show the real part and imaginary part of the energy levels. It is observed that in the range of $\gamma < \gamma_{\text{EP}}$, the initial state prepared in either the upper or lower level can perfectly follow the real part of the adiabatic energy level. However, in the range from $-\gamma_{\text{EP}}$ to $+\gamma_{\text{EP}}$, both states evolve following the imaginary part of the upper level. This is due to the so-called skin effect [47], in which in the non-Hermitian system, the eigenvalue with a positive imaginary part will dominate the dynamical evolution. More interestingly, when $\gamma > +\gamma_{\text{EP}}$, the quantum states follow neither the upper level nor the lower level, clearly indicating the breakdown of adiabaticity.

The adiabatic fidelities can be introduced to measure how close a normalized quantum state $|\psi(\gamma = \alpha t)|$ is to the adiabatic limit $|\psi^\text{ad}|$. For dynamical evolution, we take the adiabatic limit of $\delta = 0.1$ as an example.
C. Analytical deductions of the adiabatic probabilities of $P_{UL}^{ad}$ and $P_{LU}^{ad}$

In terms of $\zeta_+$ and $\zeta_-$, the formula (2) of the transition probability can be rewritten as,

\begin{align}
P_{LU}^{ad} &= \frac{\zeta_+(t \to +\infty) + \zeta_-(t \to +\infty)}{(2 - \delta)\zeta_+(t \to +\infty) + \delta\zeta_-(t \to +\infty)} , \\
P_{UL}^{ad} &= \frac{(1 - \delta)\zeta_+(t \to +\infty) - \zeta_-(t \to +\infty)}{(2 - \delta)\zeta_+(t \to +\infty) + \delta\zeta_-(t \to +\infty)} .
\end{align}

Considering that the initial state is on lower level and according to Eq. (5) and explicit expressions of the eigenstates in Eq. (10), we readily obtain

\begin{align}
\zeta_+(t) &= \frac{N(\gamma) + \sqrt{\gamma^2 + v^2(1-\delta)}}{1 - \frac{\gamma}{\sqrt{\gamma^2 + v^2(1-\delta)}}} , \\
\zeta_-(t) &= \frac{2\gamma N(\gamma)}{(\delta - 2)\sqrt{\gamma^2 + v^2(1-\delta) + \delta\gamma}} .
\end{align}

It should be noted that $N(\gamma)$ appears in the above formula and the total population is not always unitary in the non-Hermitian system.

In the weak nonreciprocal regime ($\delta < 1$), in the adiabatic limit, the quantum state evolves on the lower level. When $\gamma \to +\infty$, we have $\zeta_+(t \to +\infty) = \frac{N(t \to +\infty)}{1 - \frac{\gamma}{\sqrt{\gamma^2 + v^2(1-\delta)}}}$ and $\zeta_-(t \to +\infty) = -\frac{N(t \to +\infty)}{1 - \frac{\gamma}{\sqrt{\gamma^2 + v^2(1-\delta) + \delta\gamma}}}$. Substituting these relations into Eq. (13a), we obtain the following:

\begin{equation}
P_{LU}^{ad} = 0 \quad (\delta < 1) .
\end{equation}

Similar analysis applies to the upper level that gives $P_{UL}^{ad} = 0$ when $\delta < 1$.

While in the strong nonreciprocal regime ($\delta > 1$), the adiabatic quantum state will encounter EPs at $\gamma_{EP} = -\sqrt{\delta - 1}$, where the denominator of the expression of $\zeta_+$ in Eq. (14a) diverges. This singularity allows $\zeta_+$ to suddenly become zero at $\gamma_{EP}$. After EP, with increasing $\gamma$, we find that $\zeta_+$ remains zero while the total population $N$ will grow rapidly. This is somewhat similar to the so-called Pancharatnam phenomenon [85]. The Pancharatnam phenomenon concerns the time development of a parameter-dependent non-Hermitian two-level system and indicates that the quantum state will eventually evolve into the eigenstate of EP when the system passes through the EP slowly. Therefore, when $\gamma \to +\infty$, we have $\zeta_+(t \to +\infty) = 0$, as $\gamma_{EP} = 0$. Substituting this relation into Eq. (13a), we immediately obtain $P_{LU}^{ad} = 1$. Similar analysis applies to the upper level. We finally obtain the adiabatic LZT probability for $\delta > 1$:

\begin{equation}
P_{LU}^{ad} = \frac{1}{\delta} ; \quad P_{UL}^{ad} = \frac{\delta - 1}{\delta} \quad (\delta > 1) .
\end{equation}

The above analytic expressions are in full agreement with the numerical results, as shown in Figs. 3(c) and (d).
FIG. 7. (color online) In the presence of nonlinear interactions and in the weak nonreciprocal regime, i.e., \( \delta = 0.5 \), dynamical levels \( \varepsilon_{\text{Dyn}} \) (circles) and adiabatic levels \( \varepsilon_{\text{Eigen}} \) (solid lines). (a) and (b) present the real part and imaginary part of the energy levels for \( c = -2 \). For dynamical evolution, the system is initially prepared in the lower adiabatic levels, i.e., \( (a, b)^T = (1, 0)^T \). Here, the dynamic evolution is in the adiabatic limit \( (a = 0.01) \). In (b), \( p_i \) are the fixed points shown in Fig. 8 corresponding to the eigenstates of the energy level.

IV. ADIABATICITY OF NONRECIPROCAL LZT IN THE PRESENCE OF NONLINEAR INTERACTIONS \((c \neq 0)\)

To investigate the adiabaticity, we need to analyze the behavior of the adiabatic levels in the nonlinear model. These levels are the solution of the time-independent version of the Schrödinger equation obtained by replacing \( i\partial /\partial t \) with the energy \( \varepsilon \), i.e., \( \varepsilon \begin{pmatrix} a \\ b \end{pmatrix} = H(\gamma) \begin{pmatrix} a \\ b \end{pmatrix} \). We assume that initial state is on the lower level, then we obtain a constraint of \( |a|^2 + |b|^2/(1 - \delta) = 1 \) according to the invariant \( \zeta = 1 \). Then, we find that the eigenenergy \( \varepsilon \) satisfies the following quartic equation:

\[
A\varepsilon^4 - B\varepsilon^3 + D\varepsilon^2 + E\varepsilon + F = 0 \tag{17}
\]

where \( A = 16(2 - \delta)^2 \), \( B = 16(2 - \delta)(c(1 - \delta)(3 - \delta) - \gamma \delta + c) \), \( D = 8(2c^2(1 - \delta)(1 - \delta)(3 - \delta) + 3) - 2c(1 - \delta)(\gamma^2 + (1 - \delta)v^2) \), \( E = 48c^2(1 - \delta)^2 - 48c\gamma(1 - \delta)(\gamma^2 + (1 - \delta)v^2) \), \( F = 16c(1 - \delta)^2 - 24c^3(1 - \delta)^2 - \delta^2(\gamma^2 + (1 - \delta)v^2) \), and

\[
2\gamma c \delta \left( \gamma^2 + (1 - \delta) \left( 3 + \delta \right) - 6 \left( 1 - \delta \right)^2 \right). 
\]

When \( \delta = 0 \), the above equation reduces to that of \([10]\).

A. In the weak nonreciprocal regime \((\delta < 1)\)

We now focus on the adiabaticity in the weak nonreciprocal regime, i.e., \( \delta < 1 \). We numerically calculate the real and imaginary parts of the energy levels. In Figs. 7(a) and (b), for a nonlinearity of \( c = -2 \), we find that the energy levels undergo a dramatic change: there are four pure real energy levels in a window near \( \gamma = 0 \), where a loop appears. Notably, for reciprocal systems, the appearance of a loop breaks the adiabaticity \([10–13, 16, 81]\). The primary mechanism for the breakdown of adiabaticity is that when the state moves up to the edge of the loop, it cannot proceed any further except...
to jump to the upper and lower levels [10]. However, for the nonreciprocal system that we consider here, as shown in Figs. 7(a) and (b), eigenenergies still exist in the conjugate pair ($p_2$ and $p_3$) beyond the edge of the loop. Nevertheless, the dynamical evolution does not follow these eigenvalues.

To analyze adiabatic dynamics in the presence of nonlinear interactions, in the spirit of Ref. [12], we turn to calculate the phase plane of the classical Josephson Hamiltonian (6). In Fig. 8, we show the evolution of the classical trajectories in the plane of $(\theta, \zeta)$ as $y$ changes adiabatically. In the plane of $(\theta, \zeta)$, the fixed points of the equations of motion (7) correspond to the eigenstates that can be obtained by equating the right-hand sides of Eqs. (7)(b) and (d) to zero. At the terminal point of the loop, two fixed points merge (as shown in Figs. 8(b) and (e)), indicating that the corresponding eigenstates coalesce. The terminal points of the loop are indeed nonlinearity induced EPs that can also break the adiabaticity of dynamical evolution.

However, at nonlinear EPs, the mechanism of the breakdown of adiabatic evolution is different from that at linear EP. The breakdown of adiabaticity is intimately linked to the collision between the fixed point (i.e., $P_2$ in Fig. 8) and the additional hyperbolic point (i.e., $P_3$ in Fig. 8), where the Bogoliubov excitation frequency drops to zero [16]. Moreover, we find that the invariant $\zeta_e$ does not show a sudden change at the singularity of the nonlinearity-induced EPs.

In Refs. [12, 16], the adiabatic evolution of the fixed points as a function of level bias was proven to correspond to the adiabatic evolution of the eigenstates. Breakdown of adiabaticity occurs when two fixed points merge together and form a homoclinic orbit. The nonzero adiabatic tunneling probability can then be calculated from the nonzero classical canonical action ($\mathcal{I}_c = \frac{1}{\hbar} \int_{-\infty}^{\infty} \zeta \cdot d\theta_-$) of the homoclinic orbit. According to classical adiabatic theorem that action or the area encircled by the classical trajectory is an invariant during the slowly sweeping of $y$. Considering the invariant $\zeta_e = 1$ [or $\zeta_e = 1/(1 - \delta)$] indicating the initial state is on lower (or upper) level, the relation $\zeta_e (t \to \infty) = 1 = \mathcal{I}_c$ [or $\zeta_e (t \to \infty) = 1/(1 - \delta) - \mathcal{I}_c$] is obtained. According to Eq. (13a) [or Eq. (13b)], we have

\[
P_{\text{LU}}^{\text{ad}} = \frac{I_c}{2 - 2\delta + \delta I_c}, \tag{18a}
\]

\[
P_{\text{UL}}^{\text{ad}} = \frac{(1 - \delta)I_c}{I_c(1 - \delta)}, \tag{18b}
\]

In Fig. 9, we show the adiabatic tunneling probabilities $P_{\text{LU}}^{\text{ad}}$ obtained by directly integrating the time-dependent nonlinear Schrödinger equation and compare them with the above analytical formula calculated from the classical canonical action ($\mathcal{I}_c$) of the homoclinic orbit at an EP. Interestingly, we find that they match each other well in the weak nonreciprocal regime ($\delta < 1$).

B. In the strong nonreciprocal regime ($\delta > 1$)

The fixed points of the classical Hamiltonian correspond to the eigenstates of the nonlinear two-level system [12] only for Hermitian or weak nonreciprocal systems. In the strong nonreciprocal regime ($\delta > 1$), our numerical calculations show that the eigenstates of the nonlinear nonreciprocal Hamiltonian (1) are complex and contain nonzero imaginary parts. Therefore, in this case, the nonzero adiabatic tunneling probability cannot be viewed as the result of the collision between fixed points of the classical Hamiltonian. In the strong nonreciprocal regime, the interplay between the nonreciprocity and nonlinearity will dramatically complicate the transition dynamics. Therefore, we use a 4-5th-order Runge-Kutta algorithm to trace the quantum evolution numerically and calculate the transition probability for a wide range of nonreciprocal and nonlinear parameters.

C. Phase diagram of adiabaticity

Figure 10 shows the phase diagram of adiabaticity for a large range of nonreciprocity and nonlinearity parameters, where panels (a) and (b) show the adiabatic transition probabilities $P_{\text{LU}}^{\text{ad}}$ and $P_{\text{UL}}^{\text{ad}}$, respectively. Two regions are observed. The region where adiabaticity is maintained, the adiabatic tunneling probabilities are zero. Whereas, in the region of the breakdown of adiabaticity, the adiabatic tunneling probabilities are nonzero. In Fig. 10(a), the region where adiabaticity is maintained is approximately within parameter range $c > 0$ and $\delta < 1$. In Fig. 10(b), the region where adiabaticity is maintained is approximately within parameter range $c < 1 - \delta$ or $\delta < 1$. In the weak nonreciprocal regime ($\delta < 1$), the nonzero adiabatic tunneling probabilities are explicitly demonstrated by the classical action theory (18). In a certain region of the strong nonreciprocity, i.e., $(1 < \delta < 2; c \leq 0)$ and $(\delta > 2; c \geq 0)$ the regions framed by the gray dots in Fig. 10, we find that interestingly, the nonlinear interaction effects can be completely suppressed so that the
V. SOME REMARKS

For the non-Hermitian systems, the distinct feature is the appearance of complex eigenvalues. Thus, the time evolution of such a non-Hermitian system is no longer unitary. To trace the temporal evolution of the probability distribution, a proper normalization scheme is required. Two approaches are usually used for the normalization of a quantum state: Scheme I: normalization of the amplitudes of the wavefunction only at the end of time evolution [86]; Scheme II: normalization of the amplitudes of the wavefunction in each integration step [87–89].

Taking the present work on nonreciprocal LZT for example, in the linear case of \( c = 0 \), we find that the results obtained from the two normalization schemes are completely consistent with each other for both the adiabatic case and the nonadiabatic case. While for the nonlinear case of \( c \neq 0 \), the two normalization schemes usually lead to different results. Moreover, the results from Scheme II are usually dependent on the choice of integration step. For the adiabatic system, Scheme II can give a convergent adiabatic tunneling probability when the integration step is set to be small enough.

For most current experiments [43–47], the normalization of the wavefunction is not performed at each time step, but rather is performed at the end of the time evolution. That is, most experiments are mainly concerned with the fractions of the populations on different levels at the end of a non-unitary evolution of a non-Hermitian quantum system. Therefore, in the present work, we choose to normalize the amplitudes of the wavefunction only at the end of time evolution.

VI. CONCLUSION

In this work, we numerically and analytically investigate adiabaticity in the nonreciprocal Landau-Zener model with a nonlinear self-interaction. In this model, hopping nonreciprocity can lead to non-Hermiticity, which is distinct from the \( PT \) system for which non-Hermiticity is induced by a complex onsite potential. For the first time, we derive the Lagrangian and classical Josephson Hamiltonian of the non-reciprocal non-Hermitian system. In the adiabatic limit of parameter sweeping, a quantum state is found to still follow the eigenstate solution until it encounters the EPs that dramatically alter the tunneling process, leading to the breakdown of adiabaticity. The EPs can be formed and changed by both nonreciprocity and nonlinearity parameters. The competition between nonreciprocity and nonlinearity yields a rich variety of adiabatic quantum evolutions.

An explicit phase diagram of adiabaticity for a large range of nonreciprocity and nonlinearity parameters is obtained. The main results are summarized in Table I. Our work provides a non-Hermitian extension of the celebrated LZT model, achieves insight into the adiabatic evolution of the non-Hermitian system, and may stimulate further explorations of the non-Hermitian topological properties both theoretically and experimentally.
