ABSTRACT

The multiwavelength observation of the nearby radio galaxy M87 provides a unique opportunity to study in detail processes occurring in active galactic nuclei from radio waves to TeV γ-rays. Here we report the detection of γ-ray emission above 250 GeV from M87 in spring 2007 with the VERITAS atmospheric Cerenkov telescope array and discuss its correlation with the X-ray emission. The γ-ray emission is measured to be pointlike with an intrinsic source radius less than 4.5′. The differential energy spectrum is fitted well by a power-law function: \( d\Phi/dE = \left(7.4 \pm 1.3\right) \times 10^{-9} \ m^{-2} \ s^{-1} \ TeV^{-1} \), and is resolved in radio, optical, and X-ray regimes and shows similar morphologies at all these wavelengths. M87 is the first non-blazar AGN observed to emit TeV γ-rays, and it provides valuable insight into the acceleration of high-energy particles in astrophysical jets.

The first detection of M87 in the TeV regime was reported by the HEGRA collaboration (Aharonian et al. 2003) with a statistical significance of 4.1 standard deviations derived from observations made during 1998–1999. This detection was confirmed by the HESS collaboration (Aharonian et al. 2006a), which also

1. INTRODUCTION

The giant elliptical galaxy M87 is a nearby (~16 Mpc), powerful FR I (Fanaroff & Riley 1974) radio galaxy (Virgo A) which lies near the center of the Virgo Cluster. Its core is an active galactic nucleus (AGN) powered by a supermassive black hole of mass (3.2 ± 0.9) \( \times 10^7 \) M\(_\odot\) (Macchetto et al. 1997), emitting the first-observed plasma jet (Curtis 1918). M87 has been observed over a broad range of energies from radio waves to TeV γ-rays. Its jet

reported a year-scale flux variability and strong indications of rapid variability (2 day scale) during a high state of γ-ray activity in 2005. The imaging atmospheric Čerenkov technique provides insufficient angular resolution (few arcminutes) to resolve the M87 emission region, but the day-scale variability claimed by HESS suggests a very small region, most likely close to the core. The confirmation of such short-timescale variability is of paramount importance because of its implications regarding the source dimensions.

The rapid variability of M87 γ-ray emission would also constitute an important connection with the most common extra-galactic sources detected in the TeV regime. These are all generally considered to be BL Lacertae (BL Lac) objects with the jet pointing toward the observer (blazar). The TeV emission of M87 is now generally interpreted in the frame of the unified scheme of Seyfert galaxies (Urry & Padovani 1995). According to this scheme, FR I radio galaxies are of the same nature as BL Lac objects, but with their jet not pointing along the line of sight. Typical models assume a M87 jet misalignment around 30°–35° (Bicknell & Begelman 1996). However, superluminal motion has been observed in the compact first knot, HST-1, in the optical (Biretta et al. 1999) and radio domains (Cheung et al. 2007). To explain this requires a jet orientation closer to the line of sight (within 19°), at least at this location in the jet. The HST-1 emission also shows “blazar-like” behavior with very strong month-scale variability in the radio, optical, and X-ray wavelengths (Harris et al. 2008), much stronger than the variability observed in the nucleus or in the other knots.

The nonthermal emission of the jet is understood as synchrotron radiation from high-energy electrons, and the TeV γ-rays could result from inverse Compton scattering by the same electron population. A time correlation between the X-ray synchrotron radiation and the TeV emission is then expected. Models explain the TeV emission as originating from electrons either in the inner jet close to the core and the jet emission base (TeV blazar-type model; Georganopoulos et al. 2005; Ghisellini et al. 2005; Lenain et al. 2008; Tavecchio & Ghisellini 2008), or in the large-scale jet (Stawarz et al. 2003; Honda & Honda 2007). On an intermediate scale, it was recently proposed that the TeV emission comes from the peculiar knot HST-1 (Stawarz et al. 2006). Since the year-scale variability is established, the core region and the knot HST-1 are more likely the source of the TeV emission than the large-scale jet.

The origin of the TeV emission could also not be in the jet but in the vicinity of the central supermassive black hole of M87. The rotating magnetosphere of the black hole could accelerate particles (pulsar-type model) producing electromagnetic cascades and then TeV γ-rays by inverse Compton scattering (Neronov & Aharonian 2007; Rieger & Aharonian 2008). This model could explain a day-scale variability of the TeV emission.

An alternative model involving protons has also been proposed (Reimer et al. 2004). In this model, the TeV γ-ray emission is dominated by neutral pion production, and by proton and muon synchrotron radiation in the highly magnetized environment of the jet formation region (synchrotron-proton blazar [SPB] model). In this context, M87 would be an efficient cosmic-ray accelerator. It was even suggested that M87 is the source of most ultra-high-energy cosmic rays detected on Earth (Biermann et al. 2001). However, the SPB model predicts a quite soft spectrum in the TeV range, softer than what was recently measured by HESS and VERITAS.

Another model, involving dark matter annihilation, has also predicted TeV γ-ray emission from M87 (Baltz et al. 2000). But the variability of the flux almost excludes this scenario as the main contributor to the TeV emission. Dark matter is expected to be distributed over much larger distance scales than those implied by the recently established year-scale variability.

Studies of the variability timescale and of coincident multi-wavelength observations are very important for discriminating between these models.

2. OBSERVATIONS AND ANALYSIS

The Very Energetic Radiation Imaging Telescope Array System (VERITAS) is a γ-ray observatory located in southern Arizona. It is an array of four 12 m diameter imaging atmospheric Čerenkov telescopes, each with a 499 pixel photomultiplier tube camera covering a 3.5° field of view (Holder et al. 2006). The energy range covered extends from 100 GeV (zenith observation) up to tens of TeV.

The observations of M87 were carried out over 51 hr between 2007 February and April at elevations from 55° to 71°. In spring 2007, VERITAS was still in its construction phase. The M87 observations were performed with an array of either three telescopes (94% of the data) or four telescopes (6%). The performance of the array during this period is discussed elsewhere (Maier et al. 2007). In order to minimize systematic errors on the estimation of the flux and its variability, we do not use the data from the fourth telescope, which was not fully calibrated at this time. We processed all the data in the same way, using only three telescopes, even when data from the fourth telescope were available.

Only good-quality data were considered for the analysis. Our data selection is based on weather conditions and raw trigger rate stability. About 90% of the data (44 hr) pass our quality selection cuts. The selected data have been processed with several independent analysis packages (Daniel et al. 2007). The results presented here come from one of these packages, and the others yield consistent results. The analysis chain uses two-threshold image cleaning, stereo reconstruction, and cosmic-ray rejection based on standard image parameter cuts (Hillas 1985). The energy of each shower is reconstructed using a method based on the quantity of light measured by the telescopes and on the position of the shower core ground impact. The differential energy spectrum is unfolded using the correction factor method described in Statistical Data Analysis (Cowan 1998).

All observations were taken in “wobble” mode, tracking M87 with a 0.5° offset north, south, east, or west from the camera center. In this mode the cosmic-ray background rate is estimated using several “mirror” regions at the same distance from the camera center (0.5°) as the nominal source position. We compare the number of events with the reconstructed shower direction in these off-source regions (seven in this analysis) to the number of events in a region centered on the nominal source position. The radius of each region is 0.13°. Statistical significances are calculated using the Li & Ma formula (eq. [17] in Li & Ma 1983).

3. VERITAS RESULTS

We detected an excess of 259 ± 44 events from the direction of M87, corresponding to a statistical significance of 5.9 standard deviations. The analysis energy threshold for the average elevation of the M87 observations (66°) is approximately 250 GeV, estimated from Monte Carlo simulations. The time-averaged excess rate (0.10 ± 0.02 γ minute⁻¹) corresponds to 1.9% of the Crab Nebula rate observed at similar elevations.

Figure 1 shows the map of the excess significance in the sky region of M87. The detected source (VER J1230+123) is consistent with a pointlike source located inside the M87 galaxy. The
position of the maximum of a two-dimensional Gaussian fit of the excess is: R.A. = 12h30m46.0 ± 0\"0.6_{\text{stat}} ± 6_{\text{sys}}^{+6.0}_{-5.0} \), decl. = +12\°23\'21.4'' ± 50''_{\text{stat}} ± 1\'30''_{\text{sys}}, compatible with the position of the M87 core (R.A. = 12h30m49.4'', decl. = +12\°23\'28.6''). Figure 2 shows the distribution of the square of the angle $\theta$ between M87 and the reconstructed shower direction. The shape of the excess is compatible with a pointlike source (dashed line). The upper limit (99\%) of the intrinsic source extension has a 4.5'' radius.

The differential energy spectrum has been measured from 250 GeV to 8 TeV. Table 1 gives the differential flux and statistical error at different energies. In order to keep the reconstructed energy bias below 10\%, the flux of the lowest energy bin (250 GeV) has been estimated using only data taken at elevation above 62\° (34.8 hr of observation). The M87 spectrum obtained is consistent with a power-law spectrum: $d\Phi/dE = \Phi_0(E/\text{TeV})^{-\gamma}$, with a flux normalization constant $\Phi_0 = (7.4 ± 1.3_{\text{stat}} ± 1.5_{\text{sys}})10^{-9}$ m$^{-2}$ s$^{-1}$ TeV$^{-1}$ and a spectral index $\Gamma = -2.31 ± 0.17_{\text{stat}} ± 0.2_{\text{sys}}$. The $\chi^2$/dof of the fit is 3.0/4. Figure 3 shows this spectrum and its power-law fit, and compares them with the previous spectra measured by HESS in 2004 and 2005 (Aharonian et al. 2006a). Data points from a recent reanalysis of the HEGRA data (Götting 2006) are also shown. The results of this HEGRA reanalysis will be used hereafter.

Correlation between the spectral index and the flux have been observed in BL Lac objects such as Mrk 501 (Djannati et al. 1999) and Mrk 421 (Krennrich et al. 2002; Albert et al. 2007). Unfortunately, the $\gamma$-ray flux from M87 being so close to the sensitivity of the present generation of atmospheric Cerenkov telescopes, the uncertainties on the spectral index do not permit making any statement on a possible similar behavior.

The $\gamma$-ray flux shows significant variability from one year to another. The first panel of Figure 5 shows the integral $\gamma$-ray flux reported by the HEGRA, HESS, and VERITAS collaborations. For ease of comparison, the VERITAS flux was scaled to the energy threshold of 730 GeV commonly used by HEGRA and HESS. The integral flux above 730 GeV is estimated according to our spectral analysis result (power-law spectrum with a spectral index $\Gamma = -2.31$): $\Phi > 730$ GeV = (8.5 ± 1.5_{\text{stat}} ± 1.7_{\text{sys}})10^{-9}$ m$^{-2}$ s$^{-1}$.

The TeV $\gamma$-ray light curve consists of data points from different experiments. The preliminary result for the Crab Nebula, standard candle of the TeV astronomy, observed with VERITAS in spring 2007 (Celik et al. 2007), is in agreement with the flux reported by HEGRA (Aharonian et al. 2004) and HESS.
We estimate the value of both the variable and the steady components of the X-ray emission of M87 by fitting the TeV correlation plot with a linear relation: $\Phi_{>730\,\text{GeV}} = (88 \pm 23) \left(\frac{X_{\text{rate}} - (1.196 \pm 0.022)}{\times 10^{-9}}\right)$ and with a quadratic relation: $\Phi_{>730\,\text{GeV}} = (338 \pm 180)\left(\frac{X_{\text{rate}} - (1.142 \pm 0.042)}{\times 10^{-9}}\right)^2$. In these two equations $\Phi_{>730\,\text{GeV}}$ is expressed in m$^{-2}$ s$^{-1}$ and $X_{\text{rate}}$ in counts s$^{-1}$. Both functions fit the data well with a $\chi^2$/dof < 1. They show that the X-ray emission consists of both a dominant steady emission (1.1–1.2 counts s$^{-1}$) and a variable fraction (<20%) strongly correlated with the $\gamma$-ray emission.

The constant part of the X-ray emission is dominated by the thermal emission from the ~2 keV gaseous atmosphere of the M87 galactic halo (Forman et al. 2007). The variable part could result from synchrotron emission by high-energy particles with cooling time less than 1 yr. The emission site for the variable component must have a compact size of order 1 lt-yr or less (~5 mas at the M87 distance), or be moving at relativistic speed in a direction close to the line of sight, to explain the yearly variability recorded.

The only known M87 regions which have such characteristics are the core and the brightest knots of the jet. The Chandra X-Ray Observatory has been used to monitor the M87 jet emission in the 0.2–6 keV energy range since 2000 (Harris et al. 2006) with enough angular resolution to measure separately the flux from the different features. Figure 5 shows the light curves of the two dominant X-ray features, which are the core and HST-1. Since 2003, HST-1 has been flaring, and it largely dominates the Chandra X-ray flux. However, the variation of the flux from this knot does not seem to correlate well with the variation of the ASM RXTE signal. Between 2003 and 2005 the HST-1 X-ray emission increased by a factor of 20, whereas the variable fraction of the ASM RXTE rate changed by less than a factor of 2. The same goes for the new flux measurement with VERITAS, which clearly do not follow the X-ray light curve of HST-1.

The next brightest features of the jet observed with Chandra can explain only with difficulty the ASM RXTE rate variation, as their fluxes are significantly weaker than the HST-1 X-ray variation. Actually, the energy range of ASM RXTE (2–10 keV) is higher than that of Chandra (0.2–6 keV), and the dominant features of the ASM RXTE energy band may not be HST-1. According to the spectral analysis of Chandra data taken in 2000 (Perlman & Wilson 2005), the core was the only bright X-ray feature with a harder spectrum than HST-1. Thus, the core seems the best candidate to dominate HST-1 in hard X-rays and provide substantial ASM RXTE rate variation. Moreover, the confidence level for a positive linear correlation between the 6 month average rates of ASM RXTE and Chandra is higher for the core (90%) than for HST-1 (65%). Since the variable component of the ASM RXTE flux is likely dominated by X-ray emission from the core, and there is a strong correlation between the TeV and ASM RXTE fluxes, we conclude that the core is the most likely candidate for the source of the TeV $\gamma$-ray emission.

It is, however, surprising that the large HST-1 flare in 2005 does not show in AMS RXTE, as this implies a very soft HST-1 spectrum. There is no evidence for such a soft spectrum in the Chandra data. Unfortunately, during the flaring period of HST-1, spectral analysis of the core and HST-1 seems impossible because the flux was so strong that the bulk of the events in the image are piled, and this destroys the spectral information. Furthermore, the core is separated by only 0.86″ from HST-1, and its Chandra signal can be contaminated by the HST-1 signal. As shown in Harris et al. (2008) the small flare of the core in 2005 can be almost smoothed out by subtracting 5% of the HST-1 signal (dotted line in the third panel of the Fig. 5). This is probably indicative of

(Aharonian et al. 2006b). Thus, the differences observed with different detectors comes from real variations of the M87 flux.

Figure 4 shows the M87 $\gamma$-ray flux night-by-night during the 3 months of observation with VERITAS. No significant short-timescale variability is observed. The constant flux fit $\chi^2$ per degree of freedom (dof) is 24.3/22. The maximum deviation from the average (MJD 54,173) is only 2.2 standard deviations.

4. X-RAY/GAMMA-RAY CORRELATION

The All-Sky Monitor (ASM) on the Rossi X-Ray Timing Explorer (RXTE) has been monitoring the M87 emission between 2 and 10 keV since early 1996 (Levine et al. 1996). Measurements are performed with sequences of 90 s “dwell.” The light-curve data used here are the quick-look results provided by the ASM RXTE team on their Web site,26 dwell-by-dwell and as a daily average.

In order to check the long-term variability of the ASM RXTE signal, we sum the data by bins of 6 months using the standard practice of weighting measurements by $1/\sigma^2$, where $\sigma$ is the measurement uncertainty. The second panel of Figure 5 shows the average ASM RXTE rate for the first 6 months of each year (i.e., the period coinciding with the observation of M87 with the ground-based detectors) since 1996. The ASM RXTE light curve has similar variations as the TeV light curve shown in the first panel. Figure 6 shows the $\gamma$-ray flux, $\Phi_{>730\,\text{GeV}}$, plotted versus the ASM RXTE rate, $X_{\text{rate}}$. Taking the error bars, which correspond to the statistical error, into account, the linear correlation coefficient is 0.78 ± 0.11 (positive correlation confidence level >99.99%). The most recent analysis of the HEGRA data has been used to calculate this correlation coefficient.

A marginal correlation between the TeV $\gamma$-ray and the ASM RXTE rate was previously suggested by the Whipple 10 m telescope collaboration in 2000–2001 (LeBohec et al. 2004), and was discussed in the doctoral theses of Beilicke (2006) and of Götting (2006). Such a correlation between the TeV and hard X-ray emissions has also been detected in the BL Lac objects Mrk 501 (Djannati et al. 1999; Krawczynski et al. 2002) and Mrk 421 (Fossati et al. 2008). The correlation for these two objects is generally close to quadratic but depends on the energy range considered (Katarzynski et al. 2005).

26 See http://xte.mit.edu/asmlc/ASM.html.
the uncertainties on the core flux measurement with *Chandra* during this period.

Motivated by the long-timescale correlation between $X_{\text{rate}}$ and $\Phi_{>730\text{ GeV}}$, we searched for a similar correlation on a 5 day scale. Such short-timescale correlation had previously been suggested from earlier Whipple 10 m data (Le Bohec et al. 2003). This study was also designed to improve our sensitivity to short-timescale variations such as those reported by the HESS collaboration. Again, we express the VERITAS results as the integral $\gamma$-ray flux above 730 GeV. Figure 7 shows $\Phi_{>730\text{ GeV}}$ versus $X_{\text{rate}}$ summed on contiguous and independent 5 day scale bins. The confidence level for a positive correlation is only 82%. The statistics are too poor for us to draw any conclusion as to a possible extension of the year-scale correlation (dash-dotted line) to the 5 day scale. Simultaneous observations of M87 with VERITAS and ASM *RXTE* will continue in the coming years, providing the opportunity to investigate further such short-timescale correlation.

5. CONCLUSION

The VERITAS collaboration observed M87 in spring 2007 with an array of three telescopes. The analysis of the 44 hr of data provides a 5.9 standard deviation detection of $\gamma$-ray emission above 250 GeV. The energy spectrum is fitted well by a power-law function: $d\Phi/dE = (7.4 \pm 1.3_{\text{stat}} \pm 1.5_{\text{sys}}) (E/\text{TeV})^{-2.5 \pm 0.17_{\text{stat}} \pm 0.2_{\text{sys}}} \times 10^{-9} \text{ m}^{-2} \text{ s}^{-1} \text{ TeV}^{-1}$. The comparison of our result with the spectra reported by the HESS and the
HEGRA collaborations does not indicate a variability of the spectral index.

In most TeV γ-ray emission models, a correlation between the γ-ray and X-ray flux is expected, and the relationship can be used to distinguish between models. We have found strong evidence for such a correlation from M87. We have shown a year-scale correlation between the γ-ray flux above 730 GeV, recorded by imaging atmospheric Cerenkov telescopes during the last 10 years, and the X-ray flux in the energy range 2–10 keV recorded with ASM RXTE. Both linear and quadratic functions fit this correlation well. The poor correlation between the ASM RXTE rate variations and the dominant X-ray features (HST-1) observed by Chandra in the 0.2–6 keV energy band is surprising, but, in the light of the correlation with the TeV flux, it suggests HST-1 is unlikely to be the main source of the γ-ray emission. If the core indeed has a harder spectrum than HST-1, it could dominate in the ASM RXTE energy range, and be the most likely site of the detected TeV emission. HESS observations of M87 in 2005 were suggestive of a 2 day scale variability. The VERITAS observations in 2007 showed it to be in a lower state, and, even with a short-timescale X-ray correlation study, the statistics of this observation are insufficient to confirm such rapid variability. Further observations and multiwavelength campaigns on M87 at a range of activity states will prove important in tracking down the site of the high-energy emission, determining the particle acceleration mechanism and the relation to the blazar class of high-energy objects.

The authors are grateful to the ASM RXTE teams at MIT and at the RXTE SOF and GOF at NASA’s GSFC and especially to Ron Remillard, who provided the ASM RXTE data. We also thank Dan Harris for his comments on the Chandra observations.

VERITAS is supported by grants from the US Department of Energy, the US National Science Foundation, and the Smithsonian Institution, by NSERC in Canada, by PPARC in the UK, and by Science Foundation Ireland.
