Quantum information science promises both profound insights into the fundamental workings of nature as well as new technologies that harness uniquely quantum mechanical behavior such as superposition and entanglement. Perhaps the most profound aspect of both of these avenues is the prospect of a quantum computer—a device which harnesses massive parallelism to gain exponentially greater computational power for particular tasks. In analogy with a conventional computer, quantum computing was originally formulated in terms of quantum circuits consisting of one- and two-qubit gates operating on a register of qubits which are thereby transformed into the output state of a quantum algorithm. In 2001 a remarkable alternative was proposed in which the computation starts with a particular entangled state of many qubits—a cluster state—and the computation proceeds via a sequence of single qubit measurements from left to right that ultimately leave the rightmost column of qubits in the answer state.

Of the various physical systems being considered for quantum information science, photons are particularly attractive for their low noise properties, high speed transmission, and straightforward single qubit operations; and a scheme for non-deterministic but scalable implementation of two-qubit logic gates imagined the field of all-optical quantum computing. In 2004 it was recognized that cluster states offered tremendous advantages for this optical approach. Because preparation of the cluster state can be probabilistic, non-deterministic logic gates are suitable for making it, removing much of the massive overhead associated with near-deterministic logic gates.

Soon after these theoretical developments there were groundbreaking demonstrations of small-scale algorithms operating on four photon cluster states, cluster states of up to six photons were produced, and the importance of high fidelity was quantified. It has been recognized that encoding cluster states in multiple degrees of freedom of photons may provide advantages to computation and has been demonstrated as a promising route to high count rates and larger cluster states. However, these demonstrations have relied on a sandwich source or double pass crystal to create the cluster state, making their production unwieldy, and scalability an issue. Here, we propose and demonstrate a simple scheme which enables a path encoded qubit to be added to any photon in a polarization encoded cluster state. This is achieved using deterministic controlled-phase (CZ) gate between a photon’s polarization and path. We use a Sagnac interferometer architecture that provides a stable and practical realization of this scheme and demonstrate simple measurement-based operations on a 2 photon, 3 qubit cluster state with high fidelity.

Quantum information science promises both profound insights into the fundamental workings of nature as well as new technologies that harness uniquely quantum mechanical behavior such as superposition and entanglement. Perhaps the most profound aspect of both of these avenues is the prospect of a quantum computer—a device which harnesses massive parallelism to gain exponentially greater computational power for particular tasks. In analogy with a conventional computer, quantum computing was originally formulated in terms of quantum circuits consisting of one- and two-qubit gates operating on a register of qubits which are thereby transformed into the output state of a quantum algorithm. In 2001 a remarkable alternative was proposed in which the computation starts with a particular entangled state of many qubits—a cluster state—and the computation proceeds via a sequence of single qubit measurements from left to right that ultimately leave the rightmost column of qubits in the answer state.

Of the various physical systems being considered for quantum information science, photons are particularly attractive for their low noise properties, high speed transmission, and straightforward single qubit operations; and a scheme for non-deterministic but scalable implementation of two-qubit logic gates imagined the field of all-optical quantum computing. In 2004 it was recognized that cluster states offered tremendous advantages for this optical approach. Because preparation of the cluster state can be probabilistic, non-deterministic logic gates are suitable for making it, removing much of the massive overhead associated with near-deterministic logic gates.

Soon after these theoretical developments there were groundbreaking demonstrations of small-scale algorithms operating on four photon cluster states, cluster states of up to six photons were produced, and the importance of high fidelity was quantified. It has been recognized that encoding cluster states in multiple degrees of freedom of photons may provide advantages to computation and has been demonstrated as a promising route to high count rates and larger cluster states. However, these demonstrations have relied on a sandwich source or double pass crystal to create the cluster state, making their production unwieldy, and scalability an issue. Here, we propose and demonstrate a simple scheme which enables a path encoded qubit to be added to any photon in a polarization encoded cluster state. This is achieved using deterministic controlled-phase (CZ) gate between a photon’s polarization and path. We use a Sagnac interferometer architecture that provides a stable and practical realization of this scheme and demonstrate simple measurement-based operations on a 2 photon, 3 qubit cluster state with high fidelity.

A standard way to define a cluster state is via a graph where the nodes represent qubits, initially prepared in the \(|+\rangle \equiv (|0\rangle + |1\rangle)/\sqrt{2}\) state, and connecting bonds indicate that an entangling controlled-phase (CZ) gate has been implemented between the pair of qubits that they connect, as in Fig. 1(a) (because these CZ gates commute, the order in which they are performed is not important). Adding a path encoded qubit on a photon in a polarization encoded cluster state therefore requires a CZ gate to be implement between the polarization of the photon and its path, which must have previously been prepared in the \(|+\rangle\) state (Fig. 1(c)).

A polarizing beam splitter (PBS), that transmits horizontal and reflects vertical polarizations of light, implements a controlled-NOT (CNOT) gate on the polarization (control qubit) and path (target qubit) of a single photon passing through it (Fig. 1(c)). A CZ gate can be realized by implementing a Hadamard (\(\hat{H}\)) gate \((|0\rangle, |1\rangle \leftrightarrow |0\rangle \pm |1\rangle)\) on the target qubit before and after a CNOT gate. For a path qubit a \(\hat{H}\) can be implemented with a non-polarizing 1/2 beamsplitter (BS). However, preparation of the \(|+\rangle\) state of the path (target) qubit...
FIG. 1. A simple scheme for adding photon path qubits to a 3-qubit cluster state. (a) The linear three-qubit cluster state can be created by preparing three qubits in the \( |+\rangle \equiv |0\rangle + |1\rangle \) state and implementing a two-qubit controlled-phase (CZ) gate between each. (b) The same cluster state can be realized if we start with the state \( |\phi^+\rangle_{1,2} \equiv (|00\rangle + |11\rangle)_{1,2} \) and implement \( H_2 \otimes H_1 \), followed by CZ_{2,3}. (c) A controlled-NOT (CNOT) between the path and polarization of a single photon is straightforwardly implemented with a polarizing beam splitter (PBS); a CZ is realized by performing a \( \hat{H} \) on the target before and after the CNOT, which for a path qubit is a 1/2 beamsplitter (BS). (d) A pair of photons were produced via Type-I spontaneous parametric downconversion in a non-linear BiBO crystal: a 60 mW 402 nm ‘pump’ laser is shone into the BiBO; a single pump photon can spontaneously ‘split’ into two ‘daughter’ photons, conserving momentum and energy; degenerate pairs of photons are collected into polarization maintaining fibres (PMFs). (e) Implementation of the circuit shown in (c): the polarization entangled state \( |\phi^+\rangle_{1,2} \) is realized in post-selection by inputting a horizontal (|H\rangle) and vertical (|V\rangle) photon into a 1/2 beamsplitter; an \( \hat{H} \) on qubit 2, realized with a half waveplate (HWP), converts \( |\psi^-\rangle_{1,2} \) to the two qubit cluster state, \( (|0+\rangle + |1-\rangle)_{1,2} \); the PBS Sagnac interferometer implements a CZ between the path an polarization of photon 2 (up to a local rotation of the path qubit).

requires an additional \( \hat{H} \), and \( \hat{H} \hat{H} \) is the identity operation \( \hat{I} \); the \( \hat{H} \) after the CNOT simply implements a one qubit rotation, and is not included in our demonstration. A PBS is therefore all that is required to add a path qubit to a polarization cluster state. Measuring the path qubit in an arbitrary basis, however, requires a phase shift followed by BS, and so interferometric stability is required.

As a simple demonstration of this approach, we constructed the 3 qubit cluster state

\[
|\psi\rangle = \left( |1H\rangle_1 |1V\rangle_C - |1H\rangle_1 |1V\rangle_D \right.
- \left. |1V\rangle_1 |1H\rangle_C - |1V\rangle_1 |1V\rangle_D \right)/2
\]

The relabeling \( |1H\rangle_1 \rightarrow |1\rangle_1, |1V\rangle_1 \rightarrow |0\rangle_1, |1H\rangle_C \rightarrow |1\rangle_2 |0\rangle_3, |1V\rangle_D \rightarrow |0\rangle_2 |1\rangle_3 \) gives the state of Eq. (1).

The phase of the path qubit, \( 3 \), can be controlled by the quarter and half waveplates (HWP) inside the Sagnac interferometer; while the stability of this phase is provided by the Sagnac architecture (the visibility of the Sagnac interferometer was 99.5%). The angle \( \alpha \) of the HWP in the interferometer sets the relative phase between \( |0\rangle_3 \) and \( |1\rangle_3 \) to \( e^{i\alpha} \). The measurement basis of qubit 3 is therefore determined by \( \alpha \).

Following the principles of cluster state quantum computation, an arbitrary qubit rotation can be performed on qubit 3 (path qubit, \( j = 3 \)) by measuring qubits 1 and 2 (polarization qubits) in the basis \( \{\psi_+\}_{j}, \{\psi_-\}_{j} \rangle \) where \( \{\psi_{\pm}\}_{j} \equiv \frac{1}{\sqrt{2}}(|0\rangle_j \pm e^{-i\varphi} |1\rangle_j \rangle \). The eigenvalues \( m_j = 0 \) or \( m_j = 1 \) if the measurement outcome on qubit \( j \) is \( \psi_{+}\rangle_j \) or \( \psi_{-}\rangle_j \), respectively. The feed forward information of \( m_1 \) selects the projection of the second qubit: for \( m_1 = 0 \) (\( m_1 = 1 \)) qubit 2 will be projected on \( \psi_{+}\rangle_2 \)(\( \psi_{-}\rangle_2 \)). After these measurements, qubit 3 is in the state \( |\psi_3\rangle = \sigma_z^{m_1} \sigma_z^{m_2} R_x (\varphi_2) R_z (\varphi_1) |j\rangle \rangle \). Hence, the path qubit can be projected into any state (up to a known \( \sigma_z \) operation). The waveplate settings in front of the PBSs determine \( \varphi_1 \) and \( \varphi_2 \); simultaneous detection of the two photons at detectors \( D_1 \) and \( D_2 \) ideally results in a sinusoidal interference fringe, as a function of \( \alpha \), with a phase and amplitude that depends on \( \varphi_1 \) and \( \varphi_2 \).

Figure 2 shows the density matrix \( \rho_{\text{exp}} \), obtained via quantum state tomography, of the polarization state of the two photons after the ordinary BS in Fig. 1(e), before the path qubit is added. (Here the phase correction waveplates were set to produce the singlet state \( |\psi^-\rangle \equiv (|01\rangle - |10\rangle) \sqrt{2} \), rather than \( |\psi^+\rangle \)). It has a fidelity with the singlet state \( |\psi^-\rangle \equiv (|HV\rangle - |VH\rangle) \sqrt{2} \) of \( F = 0.895 \). A major source of this non-unit fidelity is that the BS had a reflectivity of \( R = 0.59 \); the fidelity of \( \rho_{\text{exp}} \) with the
expected output state \( |\psi'\rangle = 0.57 |HV\rangle + 0.82 |VH\rangle \) is \( F = 0.929 \). The remaining imperfections predominantly arise from the non-unit visibility of quantum interference at the ordinary BS: the measured visibility for two photons of the same polarization was \( V_{\text{meas.}} = 0.91 \), which is \( V_{\text{rel.}} = 0.97 \), relative to the ideal visibility for a \( R = 0.59 \) BS \( V_{\text{ideal}} = 0.937 \). This visibility results in reduced coherences in the measured density matrix shown in Fig. 2. These imperfections in \( \rho_{\text{exp}} \) will limit the performance of cluster state operations described below.

Figure 2 shows experimentally measured coincidence counts as a function of \( \alpha \) for several different projective measurements on (polarization) qubits 1 and 2: \( B_1(\pi/2) \otimes B_2(\pi/2) \) (red), \( B_1(\pi/2) \otimes B_2(\pi/4) \) (green), \( B_1(\pi/2) \otimes B_2(0) \) (blue) and \( B_1(\pi/2) \otimes B_2(-\pi/4) \) (black). The solid lines are theoretical prediction of the fringe expressed as \( Y(\alpha) = Y_0(1 + (1 - 2a^2) \cos(\alpha + \varphi_2) + 2a \sqrt{1 - a^2} \sin(\alpha + \varphi_2) \sin(\varphi_1)) \), where \( Y_0 \) is the peak coincidences counts from each experiments and \( a = 0.567 \) is a constant depending on the reflectivity \( R = 0.59 \) of the BS. The relation between \( R \) and \( a \) is \( a^2 = (1 - R)^2 / ((1 - R)^2 + R^2) \). The expected high visibility fringes are observed in each case (the non-unit visibility is a result of the reduced coherences in \( \rho_{\text{exp}} \) ), however the phase of each fringe is offset (10’s of degrees) compared to the case for a \( R = 0.5 \) BS but is good agreement with \( Y(\alpha) \). Taking into account the \( R = 0.59 \) BS well explains these offsets. Similar fringes were measured for other projective measurements on qubits 1 and 2: \( \{ B_1(-\pi/4), B_1(0), B_1(\pi/4), B_1(\pi/2) \} \otimes \{ B_2(-\pi/4), B_2(0), B_2(\pi/4), B_2(\pi/2) \} \) (not shown), and again the observed phases and visibilities were in good agreement with predictions based on an \( R = 0.59 \) BS. Observation of these fringes confirms the correct one-qubit rotations are realized via the measurements on the two-photon, three-qubit cluster state.

We have experimentally demonstrated a simple scheme for adding path-encoded qubits to a polarization-encoded cluster state and demonstrated simple one-qubit rotations on such a hybrid path-polarization cluster state. Similar approaches have used less stable Mach-Zehnder interferometers\(^{15} \), while 10 qubits on 5 photons have been entangled in a similar way\(^ {16} \). Photonic approaches to exploring cluster states and measurement based quantum computations are currently the most advanced. Further progress is limited by the number of photons, making schemes for encoding more than one qubit per photon appealing. The advent of high performance waveguide integrated quantum circuits\(^ {17,18} \) that include ultra-stable interferometers\(^ {17,19} \) and precise optical phase control\(^ {20} \) is a promising architecture for this approach. Our scheme uses entanglement of polarization and path degrees of freedom of one photons. This enables the addition of a path qubit to any photon in a polarization cluster state. The path qubit is not fully connected in the cluster, because the path qubit can be connected to the polarization qubit sharing same photon only. This is most useful at the edges of the cluster state. With current approaches using up to six photons, adding path qubits in this way has the potential to significantly increase the size of cluster states, and thereby the complexity of algorithms that can be implemented. However, there is some possibilities to entangle path qubits from different photons\(^ {20} \) to develop more sophisticated cluster state.
