ABSTRACT
Angular momentum is transported outwards through an accretion disc by magnetohydrodynamical (MHD) turbulence thus allowing material to accrete on to the central object. The magnetorotational instability (MRI) requires a minimum ionization fraction to drive turbulence in a disc. The inner parts of the disc around a young stellar object are sufficiently hot to be thermally ionized. Further out, cosmic rays ionize the surface layers and a dead zone forms at the mid-plane where the disc is too cool for the MRI to operate. The surface density in the turbulent active layer is often assumed to be constant with radius because the cosmic rays penetrate a constant layer. However, if a critical magnetic Reynolds number, $Re_{M,\text{crit}}$, is used to determine the extent of the dead zone, the surface density in the layer generally increases with radius. For small critical magnetic Reynolds number of the order of 1, the constant-layer approximation may be a reasonable fit. However, MHD simulations suggest that the critical magnetic Reynolds number may be much larger, of the order of $10^4$. Analytical fits for the surface density in the magnetic active layer show that $\Sigma_m \propto Re_{M,\text{crit}}^{-2} R^{9/2} T^2$, at temperature $T$ and radius $R$, are a good fit for higher critical magnetic Reynolds number. For the metallicity variation between our Galaxy, the Large Magellanic Cloud (LMC) and the Small Magellanic Cloud (SMC), there should be no significant difference in the extent of the dead zone. Observations suggest an increase in the lifetime of the disc with decreasing metallicity, which cannot be explained by the dead-zone structure (ignoring possible differences in dust abundances).

Key words: accretion, accretion discs – protoplanetary discs – stars: pre-main-sequence.

1 INTRODUCTION
Low-mass stars are thought to form from the free-fall collapse of a protostellar molecular cloud core to a protostar with a disc on a time-scale of a few $\times 10^5$ yr (Shu, Adams & Lizano 1987). Angular momentum transport in accretion discs is driven by turbulence thus allowing material to accrete on to the young star. The magnetorotational instability (MRI) can drive turbulence if the gas is well coupled to the magnetic field (Balbus & Hawley 1991). However, with a low ionization fraction the MRI is suppressed (Gammie 1996; Gammie & Menou 1998). The inner parts of a disc around a young stellar object are hot enough to be thermally ionized. However, further out, the disc becomes layered with an MRI turbulent (active) layer at each surface and a dead zone at the mid-plane that is shielded from the ionizing radiation of cosmic rays and X-rays from the star (e.g. Sano et al. 2000; Matsumura & Pudritz 2003). In this work we concentrate on circumstellar discs, but note that dead-zone formation is also favourable in circumplanetary discs (Martin & Lubow 2011a).

A frequently used assumption in calculations of discs with dead zones is that the surface density of the MRI active surface layer is constant with radius (e.g. Armitage, Livio & Pringle 2001; Terquem 2008; Matsumura, Pudritz & Thommes 2009; Zhu, Hartmann & Gammie 2009a). The cosmic rays enter the disc surface and are attenuated exponentially with a stopping depth of surface density around $100$ g cm$^{-2}$ (Umebayashi & Nakano 1988). However, this does not allow for recombination effects that may play a significant role in determining the ionization of the disc.

A more realistic way to determine the dead zone is by using a magnetic Reynolds number. Magnetohydrodynamical (MHD) simulations show that magnetic turbulence cannot be sustained if the magnetic Reynolds number is lower than some critical value $Re_M < Re_{M,\text{crit}}$ (Fleming, Stone & Hawley 2000). However, the critical value is uncertain. Simulations of Fleming et al. (2000) that compute the non-linear outcome of instability suggest that $Re_{M,\text{crit}} \approx 10^4$ without a net magnetic flux through the disc. With a magnetic flux it could be of the order of 100. Wardle (1999) and Balbus

& Terquem (2001) considered the linear stability of the discs and found that the effects of Hall electromotive forces are important and the value may be as small as \( R_{EM, crit} = 1 \). However, conditions for linear instability and for maintaining turbulence are not necessarily the same (Balbus & Hawley 2000). We consider a range of values for the critical magnetic Reynolds number from 1 to 10^4.

The surface layers of the disc may be ionized by cosmic rays or X-rays. Matsumura & Pudritz (2003) find that cosmic rays determine the extent of the dead zone under typical conditions unless the X-ray energy is very high. We consider only cosmic ray ionization and neglect X-rays. Electrons in the disc are removed through dissociative recombination with molecular ions and at a slower rate with radiative recombination with heavy metal ions. The ionization fraction, and hence the extent of the dead zone, is sensitive to the number of metal atoms because they quickly pick up the charges of molecular ions but slowly recombine with the electrons.

The typical lifetime of a protostellar disc in the solar neighbourhood, where the metallicity is \( Z \approx 0.02 \) is of the order of 3–5 Myr (e.g. Hernández et al. 2009). For stars near SN 1987A in the Large Magellanic Cloud (LMC) De Marchi, Panagia & Romaniello (2010) find from H\( \alpha \) fluxes that the mean lifetime is of the order of 13 Myr and the metallicity there is \( Z \approx 0.008 \). Note, however, that these stars are likely to be slightly more massive. Similarly, De Marchi, Panagia & Romaniello (2011) observe the NGC 346 cluster in the Small Magellanic Cloud (SMC), where the metallicity is \( Z \approx 0.002 \), and find disc lifetimes of around 20 Myr. It appears from these results that the lifetime of the disc increases with decreasing metallicity. Dead zones affect the accretion rate through the disc and thus lifetime of disc accretion and so we consider how the dead zone varies with metallicity.

In Section 2 we describe the layered disc model where the extent of the dead zone is determined with the critical magnetic Reynolds number. We consider thermal ionization, cosmic ray ionization and recombination. In Section 3 we choose a fiducial disc model and find the dead zone and resulting accretion rate through the disc for varying metallicity and critical magnetic Reynolds number. We investigate the extent to which assuming a constant surface density in the active layer can approximate this and how sensitive the dead zone is to the metallicity. In Section 4 we find analytical approximations to the surface density in the active layer of the disc.

2 LAYERED DISC MODEL

In an accretion disc (Lynden-Bell & Pringle 1974; Pringle 1981) around a central object of mass \( M \), where the material is in Keplerian orbits with angular velocity \( \Omega = \sqrt{GM/R^3} \) at radius \( R \), the kinematic turbulent viscosity may be parametrized by the \( \alpha \)-prescription

\[
v = \alpha \frac{c_s^2}{\Omega},
\]

(Shakura & Sunyaev 1973), where \( \alpha \) is a dimensionless parameter, which is not well constrained. Numerical simulations of MHD turbulence find \( \alpha \gtrsim 0.01 \) (Brandenburg et al. 1995; Stone et al. 1996; Fromang et al. 2007; Davis et al. 2009; Guan et al. 2009). Observational evidence from dwarf nova and X-ray outbursts suggests \( \alpha \sim 0.1–0.4 \) (King, Pringle & Livio 2007). In this work we take \( \alpha = 0.1 \) but discuss implications of a lower value. The sound speed is given by

\[
c_s = \sqrt{\frac{RT}{\mu}},
\]

where \( T \) is the mid-plane temperature of the disc, \( R \) is the gas constant and \( \mu = 2.3 \) is the mean particle weight. The disc is viscous only in the turbulent active surface layer of the disc, not in the dead zone.

The dead zone is determined by where the MRI is unsustained because of poor coupling of the magnetic field to the disc. If turbulence is damped on a scale of \( \lambda \), then the growth rate of the MRI is \( \lambda \sim \lambda_0 \), where \( \lambda_0 = B / (4\pi \rho)^{1/2} \) is the Alfvén speed, \( B \) is the magnetic field and \( \rho \) is the density. Hawley, Gammie & Balbus (1995) use numerical simulations to find the shear stress due to turbulence induced by the instability to be \( \omega_{\phi} \approx \rho V^2_z \). In terms of the Shakura & Sunyaev (1973) \( \alpha \)-parameter this is \( \omega_{\phi} = \alpha \rho c^2_s \) and so equating these we find \( \lambda_0 \approx c_s^3 \). The growth rate of the Ohmic diffusion is \( \eta \lambda^2 \), where \( \eta \) is the diffusivity of the magnetic field. Complete damping occurs when all turbulence scales less than the scale height, \( H = c_s / \Omega \), are damped. This means that \( \lambda < H \), or equivalently we can define the magnetic Reynolds number

\[
R_{EM} = \frac{\alpha c_s H}{\eta},
\]

and the disc is dead if \( R_{EM}(R, z) < R_{EM, crit} \). Note that several definitions of the magnetic Reynolds number have been used. For example, Fleming et al. (2000) defined it as above but without the factor of \( \alpha c_s^2 \). We consider a range of values for \( R_{EM, crit} \). The Ohmic resistivity is

\[
\eta = \frac{234 T^{1/2}}{x_e} \text{cm}^2 \text{s}^{-1}
\]

(Blaes & Balbus 1994), where the electron fraction is

\[
x_e = \frac{n_e}{n_c},
\]

where \( n_e \) is the number density of electrons and \( n_c \) is the total number density. With vertical hydrostatic equilibrium the number density is

\[
n_z = n_e \exp \left[ \frac{1}{2} \left( \frac{z}{H} \right)^2 \right],
\]

where \( z \) is the height above the mid-plane of the disc. The number density at the mid-plane of the disc, where \( z = 0 \), is

\[
n_c = \frac{\Sigma}{\sqrt{2\pi \mu m_H} H},
\]

where \( m_H \) is the mass of hydrogen. In the following two sections we consider the electron fraction in the disc with thermal ionization, cosmic ray ionization and recombination.

2.1 Thermal ionization

The dominant thermal ionization ions in protostellar discs are Na\( ^+ \) and K\( ^+ \) (Umebayashi & Nakano 1981). However, the K\( ^+ \) ion is more important at the onset of dynamically interesting ionization levels because of its smaller ionization potential. The Saha equation for the electron fraction from thermal ionization can be approximated by

\[
x_e = 6.47 \times 10^{-13} \left( \frac{10^{K/H}}{n_n} \right)^{1/2} \left( \frac{T}{10^3 \text{K}} \right)^{3/4} \times \left( 2.4 \times 10^{15} \right)^{1/2} \exp \left( -25188/T \right) \left( \frac{1.15 \times 10^{-11}}{n_n} \right)
\]

(Balbus & Hawley 2000), where \( [K/H] = \log_{10} (K/H) - \log_{10} (K/H)_{solar} \) is the potassium abundance relative to hydrogen abundance and \( \log_{10} (K/H)_{solar} = -7 \). We consider the effect of

2.2 Recombination

When thermal ionization becomes negligible, the ionization fraction is found with the balance of cosmic ray ionization and recombination effects. Electrons may be captured by dissociative recombination with molecular ions (of density $n_{M^+}$) and radiative recombination with heavy-metal ions (of density $n_{m^+}$). Charge will be transferred from molecular ions to metal atoms and so the electron fraction depends also upon the metal fraction

$$x_e = \frac{n_m}{n_n}, \quad (9)$$

where $n_m$ is the number density of metals. The standard notation for metallicity is by mass fraction, $Z$. This is related to the metal fraction with

$$x_m = \frac{Z}{\mu}, \quad (10)$$

where $\mu$ is the average mass of a particle in units of the mass of hydrogen. For example, the molecule of highest mass taking part in the reactions may be CO, which has a mass of 28 units. In our Galaxy $Z = 0.02$ so $x_m \gtrsim 7 \times 10^{-4}$. In the LMC $Z = 0.008$ is equivalent to $x_m \gtrsim 3 \times 10^{-4}$ and in the SMC $Z = 0.002$ is equivalent to $x_m \gtrsim 7 \times 10^{-5}$.

Assuming that the rates are the same for all species, the rate equation for the electron density is

$$\frac{dn_e}{dt} = \zeta n_n - (\beta_p n_{M^+} + \beta_e n_{m^+}) n_e \quad (11)$$

and for the molecular ion density

$$\frac{dn_{M^+}}{dt} = \zeta n_n - (\beta_p n_e + \beta_{m^+} n_{m^+}) n_{M^+}. \quad (12)$$

The ionization rate, $\zeta$, is discussed in the next section. The recombination rate coefficients are

$$\beta_e = 3 \times 10^{-11} T^{-1/2} \text{ cm}^3 \text{ s}^{-1} \quad (13)$$

for the radiative recombination of electrons with metal ions, $\beta_p = 3 \times 10^{-6} T^{-1/2} \text{ cm}^3 \text{ s}^{-1}$

(14)

for the dissociative recombination of electrons with molecular ions and

$$\beta_{m^+} = 3 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1} \quad (15)$$

for the charge transfer from molecular ions to metal atoms. Conservation of charge tells us that

$$n_e = n_{M^+} + n_{m^+}. \quad (16)$$

Solving equations (11) and (12) in steady state with equation (16) gives the cubic equation

$$x_e^3 + \frac{\beta_{m^+}}{\beta_{m^+}} x_m x_e^2 - \frac{\zeta}{\beta_e n_n} x_e - \frac{\zeta \beta_{m^+}}{\beta_{m^+} n_n} x_m = 0 \quad (17)$$

(Oppenheimer & Dalgarno 1974; Spitzer 1998; Millar, Farquhar & Willacy 1997), which can be solved to find the electron density. There are three solutions to equation (17) but only one that is both real and positive.

The solution to equation (17) can be simplified for the case where there is zero metallicity, $x_m = 0$, and find

$$x_e = \sqrt{\frac{\zeta}{\beta_e n_n}} \quad (18)$$

and also when the metals dominate so that $x_m \gg x_e$ and

$$x_e = \sqrt{\frac{\zeta}{\beta_e n_n}} \quad (19)$$

(see Matsumura & Pudritz 2003). We use these limits in Section 3.

We note that this model does not take the effects of dust into account that may increase the size of the dead zone (e.g. Turner & Sano 2008; Okuzumi & Hirose 2011).

2.3 Cosmic ray ionization

We consider the only external ionization source to be cosmic rays with ionization rate

$$\zeta = \zeta_0 \exp \left( - \frac{\Sigma_m}{\Sigma_{cr}} \right) \quad (20)$$

(where we have neglected the second term in the equation by Sano et al. 2000), $\zeta_0 = 10^{-17} \text{ s}^{-1}$ (Spitzer & Tomasko 1968) and $\Sigma_{cr} = 100 \text{ g cm}^{-2}$ (Umemayashi & Nakano 1988). The total surface density in the active layers is

$$\Sigma_m = 2 \mu m_{H} \int_{z_{cr}}^{\infty} n_e dz = \Sigma \text{ erfc} \left( \frac{z_{cr}}{2 \sqrt{2} H} \right), \quad (21)$$

where $z_{cr}$ is the height of the disc above the mid-plane where the dead zone ends, which we find in Section 2.5.

2.4 X-ray ionization

Young stellar objects may be active X-ray sources (e.g. Koyama et al. 1994). However, Matsumura & Pudritz (2003) find that cosmic ray ionization dominates X-ray ionization. For example, comparing their figs 2 and 3, the dead zone is much larger in both height and radius with only X-rays. X-rays may dominate only if the energy is very high, $kT_K = 5-10 \text{ keV}$, but this is much higher than for most observed sources. In this work we neglect X-ray ionization and concentrate on the effects of cosmic ray ionization.

2.5 Dead zone

We have found the electron fraction with thermal ionization and cosmic ray ionization with recombination. In order to determine the dead-zone height we take the electron fraction to be the maximum of equation (8) and the solution to equation (17). Now we can find the magnetic Reynolds number in equation (3) and for each radius, $R$, find the critical height in the disc, $z_{cr}$, by solving $R_{em} = R_{M,cr}$. This is straightforward where thermal ionization is dominant. However, it is slightly more complicated where cosmic ray ionization dominates. For example, with the high-metallicity limit for the electron fraction (equation 19) we solve

$$- \frac{1}{2} \left( \frac{z_{cr}^2}{H} \right)^2 = \ln \left( \frac{\alpha^{1/2} c_e H z_{cr}^{1/2}}{234 T^{1/2} \beta_{m^+} n_{m^+}^{1/2}} \right)^2 - \frac{\Sigma}{\Sigma_{cr}} \text{ erfc} \left( \frac{z_{cr}}{\sqrt{2} H} \right). \quad (22)$$

In the limit of low metallicity we replace $\beta_{m^+}$ with $\beta_{m^+}$. Given a total surface density and temperature, this equation can be solved numerically to find $z_{cr}$ and hence the active layer surface density given in equation (21) and the dead-zone surface density $\Sigma_d = \Sigma - \Sigma_m$. We illustrate this with an example in the next section.
3 DISC PROPERTIES

We choose a fiducial model for the disc structure around a star of mass $M = 1 \, M_\odot$ and consider properties of the dead zone. We take the total surface density to be

$$\Sigma = \Sigma_0 \left( \frac{R}{\text{au}} \right)^{-\alpha},$$

where $\Sigma_0 = 10^3 \, g \, \text{cm}^{-2}$ and the mid-plane temperature is

$$T = T_0 \left( \frac{R}{\text{au}} \right)^{-\beta},$$

where $T_0 = 100 \, K$. We choose the disc such that without the dead zone, it has a constant accretion rate at all radii. This requires $M \propto \nu \Sigma = \text{const}$ and so we take $s + t = 1.5$. Unless otherwise stated, we choose $s = t = 0.75$. This disc is in a steady state if it is supplied with a constant source of mass in the outer parts and the disc is fully MRI active. However, we now show that the disc may have a dead zone.

3.1 Active layer

In Fig. 1 we show, at a fixed radius in the disc, $R = 1 \, \text{au}$, the surface density in the active layer as a function of the total surface density. We vary the metallicity and critical magnetic Reynolds number in the disc. The dotted lines show the high-metallicity limit for the electron fraction given in equation (19). The solid lines show intermediate metallicities found by solving the cubic equation (17) for the electron fraction. For fixed radius, the active layer reaches a constant surface density as the total surface density increases. The active layer is the smallest with a low metallicity and a high critical magnetic Reynolds number.

![Figure 1](https://example.com/fig1.png)

**Figure 1.** For a fixed radius in the disc of $R = 1 \, \text{au}$, the surface density of the active layer in the disc is shown as a function of the total surface density. The upper two lines show $R_{\text{M, crit}} = 1$, the middle two lines show $R_{\text{M, crit}} = 100$ and the lower two $R_{\text{M, crit}} = 10^4$. The dotted lines show the high-metallicity limit for the electron fraction found in equation (19) and the solid lines have $x_m = 10^{-12}$ (upper solid line), $x_m = 10^{-10}$ (middle solid line) and $x_m = 10^{-7}$ (lower solid line) found by solving the cubic (17) for the electron fraction.

However, the finite metallicities considered in Fig. 1 are tiny. Even the highest finite metal fraction we consider here, $x_m = 10^{-7}$, corresponds to a very small metallicity of about $Z = 3 \times 10^{-6}$ (see equation 10) that is several orders of magnitude smaller than that in the SMC. The metallicity required for the dead zone to be significantly different from the high-metallicity limit is very small, unless the critical magnetic Reynolds number is found to be significantly larger than $10^4$. Hence, for reasonable metallicities, those in the observable universe, the dead-zone structure does not depend on metallicity and the high-metallicity limit is appropriate. In the rest of this work we consider only the high-metallicity limit.

In Fig. 2 we show the height of the dead zone as a function of radius in the disc for varying critical magnetic Reynolds number in the high-metallicity limit. As the critical magnetic Reynolds number increases, the size of the dead zone increases. The results are similar to those of Matsumura & Pudritz (2003) who find the dead zone in a disc with a different surface density and temperature distribution.

![Figure 2](https://example.com/fig2.png)

**Figure 2.** The height of the dead zone as a function of radius for critical magnetic Reynolds number of 1 (dotted line), 100 (short-dashed line) and $10^4$ (long-dashed line) in the high-metallicity limit. The solid line shows the scale height of the disc, $H$. Note that the axis scales are not the same.

In Fig. 3 we also plot the inner most parts of the dead zone and see that the effect of varying the constant $[K/H]$ (the potassium abundance relative to hydrogen abundance, see Section 2.1) is not very significant. It only affects the innermost parts of the disc where thermal ionization is the dominant source. Further out where cosmic ray ionization becomes dominant the dead zone does not depend on $[K/H]$. In the rest of the work we take the solar abundance value, $[K/H] = 0$.

In Fig. 4 we show the surface density of the active layer as a function of radius in the disc for varying critical magnetic Reynolds number in the high-metallicity limit. The inner parts of the disc are thermally ionized and the outer parts are fully ionized by cosmic rays. Hence in these regions, the surface density of the active layer is equal to the total surface density, $\Sigma_{\text{in}} = \Sigma$.

In the region where a dead zone exists, the surface density in the active layer initially decreases sharply. This is because the temperature in the disc decreases with radius ($T \propto R^{-3/4}$) and the thermal ionization decreases exponentially with temperature. However, once
the ionization through cosmic rays dominates the thermal ionization, the active layer surface density increases with radius until the whole disc is turbulent. Independently, the decreasing temperature distribution has the effect of lowering the active layer surface density in this region. However, the dominant effect is the scale height of the disc, $H$, that increases with radius ($H \propto R^{7/8}$). As described in Section 2, the turbulence is completely damped when it is damped on all scales $<H$. The damping decreases with radius because of the increasing scale height and thus the active layer surface density increases.

The constant surface density in the active layer that is more generally assumed is also plotted in the dot–dashed line in Fig. 4. We take as an example a disc which is dead if $T < T_{\text{crit}} = 1500 \, \text{K}$ and $\Sigma > \Sigma_{\text{crit}} = 200 \, \text{g cm}^{-2}$. The active surface density determined by the critical magnetic Reynolds number is very different from a constant except for a low critical magnetic Reynolds number. For $R_{\text{FM, crit}} = 1$, the surface density of the active layer is close to constant but much larger than the generally assumed values that are less than around 200 g cm$^{-2}$. The minimum surface density in the active layer, which occurs close to the inner edge of the dead zone, can be very small especially for high critical magnetic Reynolds number. This is not well represented by the assumed constant value.

### 3.2 Accretion rate

The accretion rate through the active layer of the disc is approximately given by

$$\dot{M} = 3 \pi \nu \Sigma_{\text{in}}. \quad (25)$$

In Fig. 5 we show the accretion rate as a function of radius in the disc for our fiducial model for varying critical magnetic Reynolds number in the high-metallicity limit. The thin active layer severely limits the accretion rate over the dead zone by up to several orders of magnitude compared with that through the outer turbulent parts of the disc. These discs cannot be in steady state.

The mass in the dead zone must increase in time because it is continually supplied by the active layer. With sufficient accretion on to the disc, the outer parts of the dead zone can become gravitationally unstable. The extra heating from the viscosity due to self-gravity can trigger the MRI and with the sudden increase in the turbulence a significant fraction of the disc is accreted in an outburst. After the outburst the disc cools, the dead zone reforms and the cycle repeats (Armitage et al. 2001; Zhu et al. 2009b). This outburst mechanism, known as the gravo-magneto instability, should be similar no matter how the extent of the dead zone is determined. The outbursts can be explained by plotting the accretion rate through the disc against the surface density at a fixed radius. There are two possible steady disc solutions, one that is fully turbulent and a second that is self-gravitating. Outbursts occur when there is no steady solution for a given accretion rate at a specific radius. The disc moves between the two solutions in a limit cycle (Martin & Lubow 2011b).

The typical bolometric luminosity of protostars is smaller than would be expected from the infall rate and duration of the protostellar phase (Kenyon et al. 1990). Observations of T Tauri stars suggest that at an age of around 1 Myr the accretion rate through the disc is around $10^{-8} \, M_\odot \, \text{yr}^{-1}$ (e.g. Valenti, Basri & Johns 1993; Hartmann et al. 1998). One solution to this luminosity problem is thought to be time-dependent accretion on to the star that may be caused by dead-zone formation in the disc. The disc spends the majority of its time with a dead zone and a restricted accretion rate on to the star. A low critical magnetic Reynolds number of around 1 could help to explain the observed accretion rates (see Fig. 5).
a time-dependent disc, the accretion on to the central star will be of the order of the minimum accretion rate through the disc after a viscous time-scale,

\[
t_v = \frac{R^2}{v},
\]  

(26)
at that radius. For example, at a radius of 0.1 au, the viscous timescale is short at around 450 yr. It is difficult to reconcile a model with a high critical magnetic Reynolds number to the observations of T Tauri star accretion rates unless there is a source of external heating on the disc.

4 ANALYTIC APPROXIMATIONS

Fig. 4 suggests that the surface density in the active layer above the dead zone can be approximated by a power law in radius for high critical magnetic Reynolds numbers. When the surface density is sufficiently large, the active layer surface density is insensitive to the total surface density (as shown in Fig. 1). This, however, does not translate into the active layer surface density being constant in radius. As described in Section 3.1, the dominant effect is the scale height of the disc, \( H \), that increases with radius leading to an increase in the active layer surface density.

An analytic approximation to the active layer surface density is found by neglecting the third term in equation (22) and then approximating \( \Sigma_m \propto \exp \left[ -\left( \frac{M_{\text{crit}}}{2} \right) \right] \). For cosmic ray ionization

\[
\Sigma_{\alpha, \text{crit}} = 1.36 \left( \frac{\alpha}{0.1} \right) \left( \frac{T}{100} \right)^2 \left( \frac{R_{\text{crit}}}{10^4} \right)^{-2} \left( \frac{M}{M_\odot} \right)^{-3/2} \times \left( \frac{\zeta_0}{10^{-17} \text{s}^{-1}} \right) \left( \frac{R}{1 \text{au}} \right)^{9/2} \text{ g cm}^{-2}. \quad (27)
\]

In regions where thermal ionization is the dominant source, the layer can be approximated with

\[
\Sigma_{\alpha, \text{th}} = 0.2 \left( \frac{\alpha}{0.1} \right) \left( \frac{T}{1500} \right)^3 \left( \frac{R_{\text{crit}}}{10^4} \right)^{-2} \left( \frac{M}{M_\odot} \right)^{-3/2} \times \exp \left[ -25 188 \left( \frac{1}{T} - \frac{1}{1500} \right) \right] \text{ g cm}^{-2}. \quad (28)
\]

Now we can fit the whole active layer surface density analytically. In Fig. 6 we show that the analytic approximation to the surface density in the active layer is a good fit for high critical magnetic Reynolds number, \( R_{M, \text{crit}} \gtrsim 100 \). Note that even though we have only shown one temperature and surface density distribution in this work, these fits are valid for any distribution.

The accretion rate through the layer can be approximated by

\[
M = 1.0 \times 10^{-9} \left( \frac{\alpha}{0.1} \right)^2 \left( \frac{T}{100} \right)^3 \left( \frac{R_{\text{crit}}}{10^4} \right)^{-2} \times \left( \frac{M}{M_\odot} \right)^{-2} \left( \frac{\zeta_0}{10^{-17} \text{s}^{-1}} \right) \left( \frac{R}{1 \text{au}} \right)^6 \text{ M}_\odot \text{ yr}^{-1} \quad (29)
\]
in regions where cosmic ray ionization is the dominant source. The minimum accretion rate through the disc occurs where cosmic ray ionization takes over from thermal ionization. By finding where the surface densities in equations (27) and (28) are equal, we find that this occurs at a temperature of \( T \approx 10^3 \) K. The radius corresponding to this temperature has the smallest accretion rate (see Fig. 5). As explained in Section 3.2, the accretion on to the central object will be limited by this minimum over a viscous time-scale at that radius.

If the viscosity \( \alpha \)-parameter is smaller than the value we have taken in this work, of 0.1, then both the active layer surface density and accretion rate would be smaller than predicted here (see equations 27 and 28). The disc would become even more unstable.
outbursts with FU Orionis observations the value of the critical magnetic Reynolds number may be further constrained.

6 CONCLUSIONS

A typical assumption used in time-dependent simulations of accretion discs with dead zones is that the surface density in the MRI active layer above the dead zone is constant with radius. However, when the dead zone is identified by the value of the critical magnetic Reynolds number including the effects of recombination, the active layer surface density is generally found to increase with radius. The constant layer is best reproduced with a low critical magnetic Reynolds number.

However, MHD simulations suggest that the critical magnetic Reynolds number may be much higher. For higher critical magnetic Reynolds numbers, \( \mathcal{R}_{\text{crit}} > 100 \) we have found an analytical fit to the active surface density (equations 27 and 28), which will be a useful approximation in future time-dependent calculations. The dead-zone structure is very sensitive to the value of the critical magnetic Reynolds number, as seen in Fig. 4, but the value is still uncertain and needs to be clarified in further work. However, this is complicated by the fact that the \( \alpha \)-paramater in the viscosity is also uncertain.

The metallicity variation between our Galaxy, the LMC and the SMC is not significant enough to affect the expected size of the dead zone in a disc (ignoring possible differences in dust abundances). When comparing accretion discs in our Galaxy with those in the LMC and SMC for example, the high-metallicity limit will be appropriate. In order to explain the observed difference in disc lifetimes with metallicity (e.g. De Marchi et al. 2010, 2011) some other effect must be taken into account.

ACKNOWLEDGMENTS

We acknowledge useful comments from the anonymous referee. RGM thanks the Space Telescope Science Institute for a Giacconi Fellowship. SHL acknowledges support from NASA grant NNX07AI72G. JEP thanks the Collaborative Visitor Programme at STScI for its support and hospitality.
