Abstract

Background: Common subtypes seen in Chinese patients with membranous nephropathy (MN) include idiopathic membranous nephropathy (IMN) and hepatitis B virus-related membranous nephropathy (HBV-MN). However, in some cases, the morphologic differences are not visible under the light microscope in the renal biopsy tissue.

Methods: We proposed a deep learning-based framework for processing hyperspectral images of renal biopsy tissue to define the difference between IMN and HBV-MN based on the component of their immune complex deposition.

Results: The proposed framework can achieve an overall accuracy of 95.04% for multiclass classification, which also proven to obtain a better performance compared to the support vector machine (SVM)-based algorithms.

Conclusion: IMN and HBV-MN could be correctly separated via the deep learning framework using hyperspectral imagery. Our results suggest the potential of the deep learning algorithm as a new method to aid the diagnosis process of MN.

Background

Membranous nephropathy (MN) is one of the most common causes of nephrotic syndrome in adult patients across all ethnicities, which also serves significantly to end-stage renal disease\textsuperscript{1–3}. Up-to-date data confirmed that MN makes up approximately 20–40% among all patients with nephrotic syndrome worldwide\textsuperscript{4, 5}. Most cases among MN are idiopathic membranous nephropathy (IMN), and the rest are secondary membranous nephropathy (SMN) attributed to various causes like lupus erythematosus (SLE), malignancy, hepatitis B virus infection.\textsuperscript{6} An estimated more than 257 million individuals worldwide are suffering from chronic HBV infection, leading to nearly one million deaths annually\textsuperscript{7}. HBV infection is prevalent among the Chinese population; approximately 20% of patients with HBV infection develop extrahepatic manifestations\textsuperscript{8}. Among the extrahepatic manifestations related to HBV infection, HBV-related membranous nephropathy is a common outcome of HBV infection. In the diagnosis process of MN, the most crucial part is to distinguish between idiopathic or secondary based on the patients’ laboratory examination and renal biopsy outcome, which determines the specific treatment decisions of the two as well as guides the long-term evaluating prognosis.

Conventional approaches in detecting glomerular hepatitis antigen/antibody consist of: positive immunofluorescence outcome and specific pathological features found in renal biopsy tissue using a light microscope and electron microscope. Theoretically, patients with IMN were characterized by glomerular lesions with only immune complex deposited under the epithelial and thickening glomerular basement membrane, and patients with HBV-MN were associated with cell proliferation and multiple locations immune complex deposition in addition to the glomerular basement membrane lesions.\textsuperscript{1}
However, in our previous laboratory practice, we have noticed that methods based on immunochemistry have a certain percentage of false positives, not to mention pathological features between IMN and HBV-MN on the conventional bi-dimensional image obtained by light microscope are highly identical.

Since the morphological distinction between IMN and HBV-MN is subtle, an alternative method apart from current ones is much needed. In this study, we proposed a computer-based automatic identification method using a hyperspectral microscopy system, which proved can be a sufficient supplementary approach to separate IMN and HBV-MN.

Superior to classic imaging techniques which only provides spatial information, hyperspectral imagery (HSI) is an advanced imaging technique capable of obtaining both spatial and spectral information of the target material.[9, 10] Every pixel of a hyperspectral image carries a specific value called spectral signature determined by the material being observed, which can be extracted by deep learning algorithms to analyze. IMN is a single-organ autoimmune disease, the component of its immune complex (IC) deposition is connected to IgG4 initiation in pathogenesis[11], where components of HBV-MN deposition are intimately related to hepatitis B virion. The different pathogenesis of IMN and HBV-MN provides us the possibility to identify their distinction using a hyperspectral imaging system. As an emerging imaging technique for medical applications, HSI also offers excellent potential for noninvasive disease diagnosis and surgical guidance.[9]

This study is the first time that the hyperspectral characteristics are applied for differing IMN from HBV-MN in adult patients with membranous nephropathy, after analyzing each patients’ hyperspectral image, their distinction is straightforward.

**Methods**

We retrieved 20 patients diagnosed with membranous nephropathy by clinical data and renal biopsy in China-Japan Friendship Hospital from July 2019 and September 2019, which includes 10 IMN patients and 10 HBV-MN patients. Inclusion criteria: IMN group: MN patients with unclear etiology and glomerular lesions limited to only immune complex deposited under the epithelial and thickening glomerular basement membrane; HBV-MN group: (1) serum HBV markers positive; (2) excluded other causes attribute to secondary renal disease (lupus erythematosus, drugs, toxins, other infections, or malignancy) (3) presence of detectable HBV-related antigen or antibody in renal biopsy tissue; Also (3) is the most fundamental and indispensable rule of all those listed above. In all cases, MN accompanied by other pathological patterns, for instance, diabetic nephropathy, IgA nephropathy, were ruled out.

2.1. **Sample Description**

We achieved the process of collecting glomerular characteristics for hyperspectral analysis by using routinely processed renal biopsy tissue. Each sample was stained with hematoxylin-eosin (HE), periodic acid-Schiff (PAS), Masson’s trichrome, and Jones’s silver. All renal tissue samples were observed by light and immunofluorescence microscopy beforehand, and all patients’ diagnosis was confirmed based on
current criteria. Later an experienced expert re-examined these biopsies, and all patients were eligible for consideration.

2.2. Hyperspectral Image Collection

We performed the hyperspectral imaging using a compound microscope system, where a SOC-710 portable hyperspectral imager is attached with a light microscope to obtain the HS images in the spectral range comprised between 400-1000 nm. For each patient, we randomly chose 2-3 glomeruli per slide, then manually marked out every immune complex in the subepithelial area using ENVI 14.0 for further analysis.

2.3. Image De-noising

Unprocessed HSI data usually contains high spectral noise generated by the imaging system, which can lead to undesirable effects. In this step, the de-noising process is achieved following equation (1). The concept of \( D(i,j) \) is to replace the center pixel with the average value of all pixels inside the local window where \( W \) and \( H \) represent the width and height of the filtering window, respectively.

\[
D(i,j) = \sum_{(m,n)\in B_{ij}} S(m,n)/WH
\]

Fig.1 shows a glomerulus from the 10\(^{th}\) channel of an HBV-MN patients' HS image before and after the de-noising technique. The remarkable improvement confirms the effect of reducing the system noise of HSI data.

2.4. Projection Transformation

As aforementioned, HSI data possessed hundreds of spectral channels information, hence a must-required step for utilizing HSI data is to reduce the redundant information in its spectral signature. Projection transformation is an advanced method for acquiring maximum reduced subspace of target without losing its essential information. Current projection transformation techniques include principal component analysis (PCA) and independent component analysis (ICA) and Fisher's linear discriminant analysis (LDA). However, a significant drawback of those techniques is that all of them are legitimate only when target data is subordinated to gaussian distribution. In this study, we were able to develop an alternative method named local Fisher's discriminant analysis (LFDA) that integrates the advantages of both Fisher's linear discriminant analysis (LDA) and locality-preserving projections (LPP), meanwhile bypassing the limitation of gaussian distribution.\(^{[12-15]}\)

2.5. Proposed Deep Learning Framework

Following the image de-noising and projection transformation procedures mentioned above, we constructed a deep neural network (DNN) to extract and classify the intrinsic and high-level features of
the different glomerular images\textsuperscript{[16]}. To be specific, support vector machine (SVM), extreme learning machine (ELM)\textsuperscript{[17]}, Alexnet\textsuperscript{[18]}, Resnet20\textsuperscript{[19]} and VGG19\textsuperscript{[20]} were implied on the MN database with and without the pre-processing procedures to achieve the ultimate goal of formulating an MN identification architecture that can automatically distinguish HBV-MN from IMN.

In this paper, we applied DNN to identifying glomerular disease in microscopic hyperspectral images for the first time, providing verification and supplementation for the outcome of immunofluorescence or light microscope.

## Results

Based on the LDFA-DNN method mentioned above, we achieved the comparative evaluation of the hyperspectral image data of HBV-MN with IMN from renal biopsy tissue. We collected 30 HBV-MN images and 24 IMN images from 10 patients of each case for the MN database. The size of each hyperspectral image is 696×520, with 128 channels of spectral dimension. Fig.2 (a) and (c) shown an HBV-MN and an IMN sample under the light microscope, in (b) (c) we marked out their immune complexes in the foreground, respectively. Fig.3 elaborates its corresponding immune complex deposition under an electron microscope. The side-by-side images of HBV-MN and IMN showed a high similarity of their biological features, whether under light or electron microscope. Hence we proceed with the pre-processing chain of de-noising and projection transformation to extract the intrinsic feature for further classification.

After LFDA is applied, we conducted experiments to investigate the performance of VGG networks under different dimensions of the reduced subspace. Table 1 shows that LFDA obtains the optimal classification performance for VGG networks when the dimension is 9. After de-noising all the original hyperspectral images, LFDA is applied to convert the massive HSI data into a reduced subspace. In Fig.4, (a) and (b) are the before and after projection transformation feature distribution of one testing sample. The results exhibit the effectiveness of LFDA for seeking a subspace with maximum separability for features.

| metrics | 5    | 9    | 13   | 17   | 21   |
|---------|------|------|------|------|------|
| OA (%)  | 93.17| 95.04| 91.87| 92.27| 92.95|
| Kappa   | 0.8629| 0.9006| 0.8367| 0.8458| 0.8590|

We also validated several patch sizes for the VGG network because of the significant impact it may cause on the performance of DNNs. The results in Table 2 suggest 11 × 11 is the optimal size of patches.

| Table 2. The classification performance of various patch sizes. |
For identifying HBV-MN and IMN, the database for the training and testing process are strictly separated, hence guaranteed the eligibility and consistency of comparing the performance between each method.

Table 3 presented the experiment performance of classifying HBV-MN and IMN through various approaches. Overall accuracy (OA), average accuracy (AA), and Kappa Coefficient were used to assess the result of different algorithms. In this study, the proposed framework improves the overall accuracy to 95.04% (12% more than the overall accuracy obtained by algorithms without pre-processing chain). Fig.5 shows the complete performance results obtained by each approach. Compared to conventional machine learning algorithms, deep learning models offers a better performance distinguishing HBV-MN from IMN. Furthermore, adding the de-noising and projection transformation boosts LFDA-DNNs’ performance significantly, hence validating the necessity of the pre-processing chain.

Table 3. The classification performance of the LFDA-DNN using the MN dataset.
Fig. 6 shows that in this study, LFDA-VGG19 achieves outstanding performance for separate HBV-MN from IMN. Its overall accuracy improves by 3.85% and 5.50% higher in comparison with LFDA-SVM and LFDA-ELM, respectively. However, while LFDA-Resnet20 maintains the best one-on-one classification result for HBV-MN and LFDA-Alexnet for IMN, LFDA-VGG19 presents a more stable and balanced performance to identify and distinguish the two. Therefore LFDA-VGG19 is chosen as the ideal deep learning framework for this study.

For further research purposes, we also added 10 HBV-MN patients with negative serum HBV markers into the framework to compare with previous HBV-MN patients, and the sorting result came back as low separability between serum HBV markers positive HBV-MN patients and those without serum antigens/antibodies. This suggests that the hepatitis B virus could cause extrahepatic immune complex formation/deposition without presenting serological evidence.

Discussion

WHO estimates that more than 257 million persons or 3.5% of the world population were living with chronic HBV infection [21]. Hepatitis B virus infection is a significant health problem in China. Previous cases reports have associated chronic hepatitis B virus (HBV) infection with several types of glomerulonephritis (GN). Almost all morphological forms of renal disease, including membranoproliferative GN(MPGN) [22], mesangial proliferative GN, minimal change disease, focal glomerulosclerosis, and IgA nephropathy (IgAN) have been described [23]. The most common type of GN is membranous nephropathy, and the natural history of this condition is not clear [24]. By employing a hyperspectral imaging-based architecture consists of filtering, projection transformation, high-level feature extractor, and softmax classifier, we were able to identify HBV-MN and IMN cases using a noninvasive new technique.

Compared to conventional bi-dimensional images obtained by light microscopy, the hyperspectral imaging system provides superior resolution and sensitivity as well as its capability to process mass-amount multi-dimensional images simultaneously [25, 26]. HSI technique was applied fields such as remote sensing field [27], archeology [28, 29], drug identification [30, 31], among many others. Throughout the years, its importance in biomedical fields has evolved gradually. In theory, compositions of different materials will present significant discrepancies in spectral curves [10]; therefore, curves of IMN and HBV-MN would be ready to distinguish due to their different immune complex components led by diverse pathogenesis. The hyperspectral analysis method we presented has the potential to demonstrates a wide spectral range and a high spectral resolution. Additionally, it enables the fast acquisition of a large number of hyperspectral images and data, and in combination with de-noising procedure ensures accuracy and reproducible imaging spectroscopy and spectrometry [9].

Up to date medical hyperspectral imaging has been employed in several different areas such as blood vessel visualization enhancement [32], estimation of the cholesterol levels [33], histopathological tissue
analysis $^{[34, 35]}$, identification of glioblastoma tumor $^{[36]}$. At the same time, there are no studies regarding membranous nephropathy and especially the distinction between IMN and HBV-MN.

**Conclusion**

In this study, we first propose the hyperspectral analysis as a new method for the characterization and distinction of HBV-MN from IMN, especially for cases where the discrimination is not ideal with the light microscopy. The hyperspectral imaging-based LFDA-DNN architecture could serve as an alternative method to the identification of HBV-MN as a result of its superiority in projection transformation and data classification, and it also indicated its nonnegligible potential for further application in the medical field.

**Abbreviations**

MN: membranous nephropathy; IMN: idiopathic membranous nephropathy; HBV: hepatitis B virus; DL: deep learning; HSI: hyperspectral imaging; DNN: deep neural network; LFDA: local Fisher's discriminant analysis; SMV: support vector machine; ELM: extreme learning machine
