ABSTRACT

Context. For the first time spectroscopic galaxy redshift surveys are reaching the scales where galaxies can be studied together with the nearest quasars. This gives an opportunity to study the dependence between the activity of a quasar and its environment in a more extensive way than before.

Aims. We study the spatial distribution of galaxies and groups of galaxies in the environments of low redshift quasars in the Sloan Digital Sky Survey (SDSS). Our aim is to understand how the nearby quasars are embedded in the local and global density field of galaxies and how the environment affects quasar activity.

Methods. We analyse the environments of nearby quasars using number counts of galaxies. We also study the dependence of group properties to their distance to the nearest quasar. The large scale environments are studied by analysing the locations of quasars in the luminosity density field.

Results. Our study of the number counts of galaxies in quasar environments shows an underdensity of bright galaxies at a few Mpc from quasars. Also, the groups of galaxies that have a quasar closer than 2Mpc are poorer and less luminous than in average. Our analysis on the luminosity density field shows that quasars clearly avoid rich superclusters. Nearby quasars seem to be located in outskirts of superclusters or in filaments connecting them.

Conclusions. Our results suggest that quasar evolution may be affected by density variations both on supercluster scales and in the local environment.

Key words. Quasars: general – Galaxies: general

1. Introduction

Active galactic nuclei (AGN) are believed to have evolved by mergers between galaxies that cause inflow of gas which fuels the growth of the black hole. According to the theory of quasar formation by Hopkins et al. (2005b), there are frequent mergers between galaxies during the hierarchial growth of structure. Mergers that involve gas-rich galaxy progenitors produce inflows of gas that cause starbursts. High gas densities fuel the black hole growth, and the galaxy is seen as a luminous infrared galaxy (LIRG). As the black hole mass increases, the feedback energy starts to expel the gas fueling accretion. The galaxy is then seen as an optical quasar. Finally the feedback of the active galactic nucleus terminates further black hole growth, after which the galaxy becomes an ordinary galaxy with a dead quasar. Although this is the prevailing paradigm for quasar evolution, it is also possible that it may not be the only mechanism for initiating activity for all types of active galaxies. Activity may also be triggered by secular processes, such as bar instabilities (Sellwood & Moore 1999).

One way of testing different theories for nuclear activity is to study the environments of AGN. If mergers are important to quasar activity, the environments of quasars should allow mergers to happen. In clusters that have a high velocity dispersion galaxies do not have enough time to merge, and therefore these should not be as likely locations for quasars as small groups of galaxies that usually have lower velocity dispersions (Hopkins et al. 2005b).

It is well known that environmental density affects properties of galaxies; an example of that is the morphology–density relation (Dressler 1980). This dependency has been studied, e.g., by Kauffmann et al. (2004). Their results show that the stellar mass of galaxies increases and their star formation rate decreases with the growth of the local density. They also find that a larger fraction of galaxies host AGN in low-density environments. It is obvious that morphologies, colors, and star formation rates of galaxies are related to the assembly history of their halos (Maulbetsch et al. 2007).

Another reason to study the environments of quasars is to test the unification schemes of different types of objects (Coldwell & Lambas 2006). Different types of AGN are thought to be physically similar objects that are viewed from different directions (Antonuccci 1979). If this is true, all AGN should have similar environments since the properties of the environments do not depend on the viewing angle. It is also possible that mergers are more important to the evolution of some types of AGN while others might be triggered through other mechanisms. Activity and luminosity of the AGN may play an important role that give clues for their merger history and associated environment.

Earlier studies of the AGN environments have mostly used galaxy counts in the fields of individual objects. The first results were from Bahcall et al. (1969) who showed that five quasars lie within the approximate geometrical boundaries of clusters of galaxies. Later much work has been done to estimate the spatial galaxy–galaxy cross-correlation amplitude; this was initiated by Longair & Seldner (1979). The correlation studies have shown that quasars mostly occupy enhanced local densities, such as
groups or clusters of galaxies. For example, De Robertis et al. (1998) found that the environments of Seyfert 2 type galaxies are not different from the control sample of normal galaxies, while the environments of Seyfert 1 galaxies are clearly poorer. The environments of BL Lac objects have been studied by Smith et al. (1995) and Wurtz et al. (1997). Both these studies show that BL Lac objects lie in poor environments, usually in clusters of the Abell richness class 0 or less. According to McClure & Dunlop (2001) radio galaxies are distributed quite evenly over all cluster richness levels, but quasars are more frequent in poor environments. This was also found by Wold et al. (2000); their results show that although there are a few quasars in rich environments, most of them seem to prefer galaxy groups or clusters of the Abell richness class 0. As a summary, most AGN lie in very poor clusters, with only a few more companion galaxies than are found in the background field, for a few hundred kpc scale.

The Sloan Digital Sky Survey (SDSS) offers new possibilities to study the large-scale structure of the Universe. As concerns the study of the environments of quasars, SDSS contains not only data for detailed studies of individual targets, but the large number of quasars and galaxies makes it possible to study these environments on larger scales than before.

Li et al. (2006) have measured AGN–galaxy cross-correlations for a large sample of quasars and galaxies in the SDSS Data Release 4. They find that on the scales between 100 kpc and 1 Mpc AGN hosts are clustered more weakly than inactive galaxies, while at smaller scales their clustering is slightly stronger. Their explanation for this result is that AGN reside preferentially at the centers of dark matter halos.

A slightly different approach was used by Miller et al. (2003), who studied the fraction of galaxies that possess an AGN, as a function of the environment. They used galaxies in the redshift range $0.05 \leq z \leq 0.095$ with the absolute magnitude $M < -20.0$ from the Early Data Release of the SDSS. Their main result is that $\sim 40\%$ of galaxies in their sample have an AGN, and they do not find any relation between the AGN fraction and the local galaxy density.

One of the most extensive studies of the environments of nearby quasars was done by Coldwell & Lambas (2006). They used quasars and galaxies at redshifts less than 0.2 in the third Data Release of the SDSS in order to study the properties of galaxies in the environments of quasars. Their main results are that nearby quasars avoid high density regions, and that the galaxies close to quasars usually have a disc-type morphology and a high star formation rate.

As the data volume provided by the SDSS has increased, environments of quasars have become an increasingly popular subject to study. One of the latest studies was done by Strand et al. (2008), who compared the environments of quasars to the AGN chosen from the photometric galaxy sample of the SDSS Data Release 5. The galaxy densities were measured from the photometric catalog that contains much more galaxies than the spectroscopic sample, but the lower accuracy of redshifts limits the analysis. Their main result is that quasars lie in higher density regions than the AGN at scales of less than 2 Mpc.

In this paper we extend the previous studies to the galaxy group and supercluster scales. We study the environments of quasars at three different scales. First we concentrate on galaxies around quasars, analysing the number density of galaxies at different distances from quasars. At the next scale, we study the relations between the group properties and the distance of its closest quasar. For the largest scale in this study, we use the luminosity density fields, which we have constructed from the galaxy catalogs. This allows us to describe the locations of quasars at supercluster scales. Throughout this work we assume $\Omega_m = 0.3$, $\Omega_{\Lambda} = 0.7$, and $H_0 = 100h$ km s$^{-1}$ Mpc$^{-1}$. Absolute magnitudes are given for $h = 1$.

2. Data

In this paper we use the spectroscopic catalogs of quasars and galaxies from the fifth (DR5) and sixth (DR6) Data Releases of the SDSS (Adelman-McCarthy et al. 2007). The original SDSS-DR5 galaxy sample contains 674749 galaxies, and the original quasar sample contains 90611 quasars. The DR6 contains 790,220 galaxies. We use three different samples: volume limited samples of galaxies from the DR5 for estimating the number densities of galaxies, volume limited samples of groups of galaxies from the DR6 for studying the group properties, and a magnitude limited sample of galaxies for studying the supercluster scales.

The final data for galaxies in this paper comes from the Tago group catalog (Tago et al. 2008) that is based on the main galaxy sample obtained from the SDSS Data Archive Server, with 488725 galaxies. Applying the lower ($z = 0.009$) and upper ($z = 0.12$) redshift limits and excluding several duplicate galaxies in the original data the number of galaxies was reduced to 387063.

To study how nearby quasars are located among galaxies we extracted four volume limited subsamples of galaxies with the absolute magnitude limits of $M_{\text{gal}} < -21.0$, $M_{\text{gal}} < -21.5$, $M_{\text{gal}} < -22.0$, $M_{\text{gal}} < -22.5$ (Petrosian r-magnitudes). The samples contain 106378, 37181, 7790 and 985 galaxies, respectively. For the limit $M_{\text{gal}} < -21.0$ the co-moving distance is chosen to be less than 500 h$^{-1}$Mpc, while the lack of very nearby quasars sets a lower distance limit of 200 h$^{-1}$Mpc. The value for $M'(r)$ for galaxies in the SDSS is $-20.44$, and therefore our samples consist of the brightest end of the luminosity function (Blanton et al. 2005).

The final group catalog we use for our group analysis is a volume limited sample based on the DR6 with the magnitudes $-22.0 < M_{\text{group}} < -21.0$. This sample contains 9581 groups, and extends up to the co-moving distance of 450 h$^{-1}$Mpc. Groups in the SDSS DR6 have been defined applying the well-known Friends-of-Friends cluster analysis method introduced by Turner & Gott (1976), and modified by E. Saar. In this algorithm galaxies have been linked into systems using a valuable linking length. By this definition a galaxy belongs to a group of galaxies if this galaxy has at least one group member galaxy closer than the linking length. In a flux-limited subsample the linking length was increased along with distance in order to keep virial properties, such as virial radius, maximum size in the sky projection and velocity dispersion similar at all distances. In the volume limited subsample that was used in this study, the linking length was constant inside one particular subsample, but was changed from subsample to subsample of various absolute magnitude limits in order to keep the virial properties similar in all volume limited subsamples.

Finally we use the Tago et al. (2008) magnitude limited sample of galaxies for determining the luminosity density field. The limiting magnitudes of the complete spectroscopic sample of the SDSS catalog used here are 14.5 and 17.77 in r band. See Tago et al. (2008) for the description of the selection effects taken into account for this magnitude-limited galaxy sample.

As our final quasar data we use the value added quasar catalog based on the DR5 (Schneider et al. 2007), which contains
77429 quasars. These quasars have the absolute i band magnitude $M_i < -22.0$, and have emission lines with line widths larger than 1000 km/s. With these conditions the sample should contain only classical quasars, while the original SDSS quasar catalog contains also other kinds of active galaxies. Due to the limits of our galaxy and group catalogs we include only quasars at the redshifts $0.078 < z < 0.172$. We also require the quasars to satisfy the target selection flag BEST, which marks the results obtained using the latest photometric software on the highest quality data. These conditions limit our sample to 174 quasars.

3. Results

3.1. Galaxies and quasars

We study the spatial density of galaxies around quasars at different scales and using different limiting magnitudes for the galaxies. As a control sample we use the same galaxy catalogs that are used for obtaining the density.

![Fig. 1. The spatial density of galaxies at radii $r < 4 \, h^{-1}\text{Mpc}$ around quasars (solid line, with errorbars) and galaxies (dashed line) for the galaxy luminosity limits $M < -21.0$ (top) and $M < -21.5$ (bottom).](image)

As a first simple measure of the density we estimate the redshift space distance from each quasar to the nearest galaxy brighter than $M = -21.5$. The average distance between a quasar and its nearest galaxy is $(4.9 \pm 0.3) \, h^{-1}\text{Mpc}$, while the average distance between a $M < -21.5$ galaxy and the nearest other galaxy is $(4.30 \pm 0.02) \, h^{-1}\text{Mpc}$. Although this estimate is quite uncertain, it may be a hint of quasars lying in less dense regions than galaxies with $M < -21.5$ in general.

Then we estimate the number density of galaxies at different distances from the quasars. We count the number of galaxies in $0.1 \, h^{-1}\text{Mpc}$ bins from 0.1 to $4 \, h^{-1}\text{Mpc}$ distance from each of the quasars. This number is then divided by the total co-moving volume of this bin for all the quasars.

$$\frac{dN}{dV}(R_i) = \frac{\frac{1}{n} \sum_{j=1}^{n} N_j}{V(R_i) - V(R_{i-1})}$$

where $n$ is the number of quasars, $N_j$ is the number of galaxies at a distance $R_i$ from each quasar, and $V(R_i)$ is the co-moving volume of a sphere with the radius $R_i$. This gives the number density of galaxies in this distance bin for all the quasars. The same calculation is done for the reference galaxies.

![Fig. 2. Distribution of the number of galaxies inside $4 \, h^{-1}\text{Mpc}$ radii from quasars (solid line histogram) and galaxies (dashed line histogram) with limiting magnitudes $M < -21.0$ (top) and $M < -21.5$ (bottom) for the galaxies.](image)

Figure 1 shows the mean number density of galaxies as a function of distance from quasars and from galaxies. The results hint at a galaxy overdensity at the radii less than $1 \, h^{-1}\text{Mpc}$ around quasars. However, because of the small number of quasars in our sample the Poissonian errors at the radii $< 4 \, h^{-1}\text{Mpc}$ are large, and the differences between quasars and galaxies are within the error limits.
In order to study the galaxy density inside the whole comoving volume enclosed by the $4\,h^{-1}\text{Mpc}$ radius from the quasars we find the distribution of the number of galaxies inside this radius. The results for the environments of quasars and galaxies for the magnitude limits $M < -21.0$ and $M < -21.5$ are shown in Fig. 2. Of the quasars in our sample, 28% have no $M < -21.0$ galaxies inside the $4\,h^{-1}\text{Mpc}$ radius, while for the $M < -21.0$ galaxies themselves, this fraction is only 21%. The Kolmogorov-Smirnov test (Table 1) shows that the distributions are different on the 98.6% significance level. This suggests that the quasars reside in poorer environments than the $M < -21.0$ galaxies. Differences in the distributions for the limiting galaxy magnitude $M < -21.5$ are less significant, but Fig. 2 shows that the fraction of quasars with no galaxies within the $4\,h^{-1}\text{Mpc}$ radius is slightly larger than the fraction of galaxies. For magnitude limits $M < -22.0$ and $M < -22.5$ the number of galaxies is too small to show any differences.

Figure 5 shows the spatial density of galaxies around quasars on larger scales, from 2 $h^{-1}\text{Mpc}$ to 30 $h^{-1}\text{Mpc}$. This was calculated in the same way as the galaxy density on smaller scales, but the bin is now $4\,h^{-1}\text{Mpc}$. Here we use two more magnitude limits for galaxies, $M < -22.0$ and $M < -22.5$. On this scale quasars are located in less dense regions than galaxies on average. When the galaxy luminosity limit increases from $M < -21.0$ to $M < -22.5$, the difference between the quasar and galaxy environments grows.

We also calculated the number densities for a volume-limited sample of galaxies with $M < -20.0$. This sample extends only up to $316\,h^{-1}\text{Mpc}$ which limits the number of quasars to 11. Underdensity around quasars can be detected, but there are not enough data to give accurate results.

The underdensity around quasars can also be seen in Fig. 4 that shows that the number of galaxies closer than $10\,h^{-1}\text{Mpc}$ to quasars tends to be lower than the number of other galaxies closer than $10\,h^{-1}\text{Mpc}$ to galaxies. For $M < -21.0$ galaxies, 45% of quasars have less than ten galaxies within the $10\,h^{-1}\text{Mpc}$ distance, while of the $M < -21.0$ galaxies themselves, only 33% belong to this group. The effect is stronger for brighter galaxies. For the magnitude limit $M < -22.0$, 50% of quasars have no galaxies within the $10\,h^{-1}\text{Mpc}$ distance, while 30% of the $M < -22.0$ galaxies have no other galaxies with the same magnitude limit closer than $10\,h^{-1}\text{Mpc}$. As we can see in Table 1, the distributions at all the magnitude limits are different at very high levels of significance.

We have made the number density analysis also for a smaller subsample of the galaxy catalog in order to estimate the effect of the edges of the sample volume. We chose 15 subsamples from the galaxy catalog with the limiting magnitude $M < -21.5$, such that all the galaxies in the subsamples lie at least at $60\,h^{-1}\text{Mpc}$ from the edges of the full sample. The number densities of these galaxies compared to the whole galaxy sample is shown in Fig. 5. This analysis showed us that the estimate of the number density is not significantly biased by the edges of the sample for distances less than $20\,h^{-1}\text{Mpc}$. For the neighbor distance $50\,h^{-1}\text{Mpc}$ our estimate is approximately 30% too small.

### Table 1. Kolmogorov-Smirnov test statistics for distributions of the number of galaxies inside 4 and 10 $h^{-1}\text{Mpc}$ radii around quasars and galaxies. Probabilities for the distributions to be similar are shown in the fourth column.

| Magnitude Limit | Distance Limit [$h^{-1}\text{Mpc}$] | $D$     | Probability |
|----------------|-------------------------------------|---------|-------------|
| $-21.0$        | 4                                   | 0.118   | 0.01442     |
| $-21.5$        | 4                                   | 0.086   | 0.1467      |
| $-21.0$        | 10                                  | 0.141   | $1.746 \times 10^{-3}$ |
| $-21.5$        | 10                                  | 0.139   | $2.176 \times 10^{-3}$ |
| $-22.0$        | 10                                  | 0.203   | $1.227 \times 10^{-6}$ |
| $-22.5$        | 10                                  | 0.197   | $1.621 \times 10^{-5}$ |

**Fig. 5.** Edge effects in the galaxy samples. Number density of all galaxies is shown with the solid line, and number density of galaxies in the 15 subsamples with the minimum distance to edges of the whole galaxy sample of 60 $h^{-1}\text{Mpc}$ or more with the dashed line.

#### 3.2. Groups and quasars

Our volume limited group catalog contains 9581 groups, but a great majority of them are groups of only two galaxies. In some cases we will use a subsample of the 777 groups that have 4 or more galaxies. This way we can see if the properties of rich groups near quasars differ from the properties of poor groups.

We study the distribution of groups of galaxies in the environments of quasars in a similar manner as we did for the distribution of galaxies. The average distance from a quasar to the nearest group is $(7.8 \pm 0.5)\,h^{-1}\text{Mpc}$ and the average distance from a galaxy with $M < -21.5$ to the nearest group is $(6.49 \pm 0.04)\,h^{-1}\text{Mpc}$. This result suggests that quasars are farther from the groups than galaxies on average. However, if we compare only the distances to the richer groups we find no difference at all: The average distance from a quasar to the nearest group of at least 4 galaxies is $(22 \pm 2)\,h^{-1}\text{Mpc}$, while the average distance from a $M < -21.5$ galaxy to the nearest rich group is $(21.64 \pm 0.08)\,h^{-1}\text{Mpc}$.

The average luminosities and numbers of galaxies of groups that have quasar or galaxy neighbors at a given distance are shown in Fig. 6. The galaxy sample used for comparison has the limiting magnitude $M < -21.0$. The plots in the top part of Fig. 6 are cumulative; e.g., the values at $R = 5\,h^{-1}\text{Mpc}$ are the averages for all the groups that have at least one quasar or galaxy neighbor closer than $5\,h^{-1}\text{Mpc}$. The mean luminosity of all the groups in the sample is $5.64 \times 10^{10}L_\odot$, and the mean number of galaxies in the groups is 2.38. Both curves approach the average for all groups as the neighbor distance grows.

Figure 6 suggests that the groups that have a quasar at a distance less than $2\,h^{-1}\text{Mpc}$ have very low luminosities and small numbers of galaxies. This result is uncertain because the number of these groups is small, only 14 groups have quasars at...
Another feature that can be seen in the figure is that the groups that have quasar neighbors at distances of 10 to 15 $h^{-1}$Mpc are brighter and richer than the groups that have bright galaxy neighbors at the same distances. This can be seen also in the differential plot, shown in the bottom panels of Fig. 6. The richest and most luminous groups are the ones that have a quasar neighbor at distances from 5 to 15 $h^{-1}$Mpc. However, the differences are small, and because of the small number of quasars, it is uncertain if the correlations are real.

In groups of only two or three galaxies the velocity dispersion does not tell much about the actual physics of the group. If we consider the subsample of rich groups of four or more galaxies, we can study dynamical properties of the groups. Figure 7 shows the average luminosities, numbers of galaxies, and rms velocities for the rich groups that have quasar neighbors closer than $R$.

If we consider only the rich groups, we see the same rise in the luminosity and the number of galaxies as we saw in the case of all the groups that have quasar neighbors closer than 10 $h^{-1}$Mpc. The rich groups that are very close to a quasar are clearly poorer and less luminous than the rich groups in general. The richest and the most luminous groups have their closest quasar at approximately 10–15 $h^{-1}$Mpc from the group. This effect can also be seen in the rms velocities, although it is not as clear as in the luminosity and the number of galaxies.

The rise in the group richness and luminosity at the 10–15 $h^{-1}$Mpc distance from quasars could be explained by the distribution of quasars within the large scale structure. The richest groups usually lie in the cores of superclusters, and 10 $h^{-1}$Mpc is a typical distance between a core and a filament (Einasto 2007b). Therefore, this result could be explained by quasars being located preferentially in filaments.

### 3.3. Superclusters and quasars

The largest density enhancements in the Universe, superclusters and their environments, can be studied using the luminosity density field of galaxies (Einasto et al. 2003). It has been shown that the morphological properties of galaxies depend on their large-scale cosmological environment (Einasto et al. 2007a and references therein). Both the local (group or cluster scale) and global (supercluster scale) environments influence galaxy morphology and their star formation activity. Rich superclusters contain a higher fraction of early type, passive, red galaxies than poor superclusters (Einasto et al. 2007b). Inside rich superclusters galaxy properties also vary. The core regions of rich superclusters contain a larger fraction of early-type red galaxies and richer groups than the outskirts of superclusters (Einasto et al. 2008). Galaxy clusters in the high-density environments are about 5 times more luminous than in the low-density environments (Einasto et al. 2005).

The luminosity density field smoothed to appropriate scales allows us to study the locations of nearby quasars in the supercluster-void network. Voids, filaments and superclusters have characteristic density levels within the overall large-scale structure; thus, the density level can be used to discriminate between different details of the network. In this procedure we use all the SDSS DR5 galaxies from the Tago catalog of groups and isolated galaxies (Tago et al. 2008). This catalog is suitable for tracing the supercluster-void network; groups are mostly density enhancements within filaments and rich clusters are high density peaks of the galaxy distribution in superclusters (Tago et al. 2008 and references therein).

We assume that every galaxy is a visible member of a density enhancement (a group or a cluster). We correct the galaxy luminosities by a weighting factor that accounts for the expected group galaxies outside the visibility window:

\[
L_{\text{tot}} = L_{\text{obs}} W_L, \tag{1}
\]

where $L_{\text{obs}}$ is the luminosity of an observed galaxy and $W_L$ is the ratio of the total luminosity to the luminosity in the visibility window $L \in [L_1, L_2]$:

\[
W_L = \frac{\int_0^{L_2} \phi(L) dL}{\int_{L_1}^{L_2} \phi(L) dL}; \tag{2}
\]

$\phi(L)$ is the galaxy luminosity function. According to Fig. 11 in Tago et al. (2008), the parameter $W_L$ is less than two at the distances from 100 to 300 $h^{-1}$Mpc, and rises up to 5 at 500 $h^{-1}$Mpc.

Finally, group and cluster galaxies are positioned at the mean group–cluster distance, to correct for the effect of the dynamical velocities (redshift space fingers).

Next a Cartesian grid is defined in the survey volume and the luminosity density field on the grid is calculated using the B-spline kernel function. Each galaxy contributes its luminosity to the density field. This gives us the total luminosity density field of the survey where different characteristic structures have different density levels.

The total luminosity in a subvolume can be calculated by summing over all the grid vertices it contains (the luminosity density units are $1.0 \times 10^{10}/(D^3)(L_\odot/(h^{-1}\text{Mpc}^{-3}))$, where \(D\) is the grid cell size in Mpc/h). Using an appropriate mass-to-luminosity ratio one can translate luminosities into masses. We chose the cell size of 1 $h^{-1}$Mpc, as this is the characteristic size of a cluster. The half-width of the B3 smoothing kernel was 16 $h^{-1}$Mpc, and the effective smoothing radius (the kernel half-width for which the density value differs considerably from zero) is 8 $h^{-1}$Mpc.

This is an appropriate way to characterize the global environment and superclusters (Einasto et al. 2007b).

Regions of $D_L < 1.5$ times the mean density are considered to be voids. Superclusters are systems that occupy regions above the threshold density about $D_L > 4.6$ (Einasto et al. 2007a). This is approximately the lowest limit for separating non-percolating galaxy systems (poor superclusters) from the overall density field. Densities which correspond to rich superclusters have a median value of $D_L = 7.5$ times the mean density and $D_L > 10$ correspond to cores of rich superclusters (Einasto et al. 2007b). These values were determined for the 2dFGRS data, and there may be some differences for the superclusters in the SDSS. However, the differences should not be large enough to influence our analysis.

Figure 8 shows the projected luminosity density field of the SDSS DR5 northern and equatorial samples. Red regions show the most luminous centers of the superclusters with densities of about 20 times the mean luminosity density. The circles in the figure represent quasars. As we see, visually quasars seem to be located in low density regions, in the outskirts of superclusters.

A more detailed analysis reveals that the local mean luminosity density around quasars is about 2.4 times the mean luminosity $D_L$ (in units of mean luminosity density). This is illustrated in Fig. 9 that shows the distribution of the mean luminosity density at quasar locations (in a ball of the radius of 2 $h^{-1}$Mpc) – the number of quasars with a given environmental density.

Most of the quasars seem to be located in a low density environment on these scales. Quasars avoid densities which are characteristic for poor superclusters, $D_L > 4.6$, and none is found in high density environments, $D_L > 10$. 

\[
R < 2 h^{-1}\text{Mpc}. \tag{3}
\]
Figure 10 shows the mean luminosity density of galaxies in north and equatorial samples around quasars as a function of distance. Two different threshold densities, \( D_L > 4.6 \) and \( D_L > 10 \) are used to separate poor and rich superclusters. As we see, regions with \( D_L > 4.6 \) belong to the nearby quasar environments. When the threshold value is increased to \( D_L > 10 \), no nearby quasars are found. If we increase the threshold value even higher, the high density regions are mostly located at the distance of approximately \( 10 h^{-1} \text{Mpc} \) from the quasars. This is close to the distance found in the analysis based on the volume limited galaxy sample in section 3.2. This scale agrees with the characteristic scale for superclusters and void sizes found in observations and simulations. (von Benda-Beckmann et al. 2008; Ceccarelli et al. 2008; Gottlöber et al. 2003).

This characteristic distance is clearly seen also in Fig. 11 which shows the \( D_L \) values for the full luminosity density grid versus the distance to the nearest quasar. In both panels of Fig. 11 we see the highest luminosity densities for the distances of about \( 10 h^{-1} \text{Mpc} \) from quasars. Differences between northern and equatorial samples in Figs. 10 and 11 are most probably due to quantitative and intrinsic variance of the relatively large and complex filamentary structures of the superclusters between two samples of different sizes. Volume of the equatorial sample is about half of the northern one. Differences between these samples are seen also in Fig. 8. This analysis indicates that nearby quasars avoid high density regions and prefer poor superclusters, outskirts of rich superclusters and filaments.

![Fig. 9. The number of nearby quasars with a given environmental luminosity density \( D_L \) (in a ball of the radius of \( 2 h^{-1} \text{Mpc} \)).](image)

The most luminous galaxies as well as the richest groups are located in core regions of rich superclusters (Einasto et al. 2007b). This is in accordance with the findings that quasars avoid rich groups and prefer filaments near superclusters. Thus our luminosity density analysis agrees with our result in sections 3.1 and 3.2 where we showed that the galaxy number density around QSOs is a function of the luminosity of galaxies.

4. Discussion

One of our main results is that nearby quasars are located in low density environments among luminous galaxies on a few Mpc scale. This confirms the result by Coldwell & Lambas (2006) for quasars in the same redshift range as here. Strand et al. (2008) find that quasars are located in more dense regions compared to other types of active galaxies. They studied environments of quasars at scales < 2 Mpc, while we analysed mostly larger scales. Moreover, we studied only the distribution of bright galaxies. It may be possible that the density of fainter galaxies in the close environments of quasars is higher.

There are several studies which demonstrate that the properties of galaxies and dark matter halos depend on their environments in several ways (Kauffmann et al. 2004; Harker et al. 2006; Balogh et al. 2004; Tempel et al. 2008). For example, Constantin et al. (2008) state that void and cluster galaxies follow different evolutionary paths, a point which should apply to active galactic nuclei as well. Presumably, the accretion process for the supermassive black hole (SBH) in a galaxy center also differs for distinct environments.

There is an observationally well justified relation for the masses of the SBH and the bulge velocity dispersion of the host galaxy (e.g. Magorrian et al. 1998; Graham et al. 2001; Tremaine et al. 2002). McLure & Dunlop (2004) applied this relation for estimating the BH masses for the 12698 quasars in the first release of the SDSS, and found that quasar SBH masses lie between \( \sim 10^7 M_\odot \) and \( \sim 10^9 M_\odot \). The connection between the growth of the black holes and the underlying structure formation was shown by Ferrarese (2002). She pointed out that the mass of the SBH correlates with the mass of the dark matter halo in which they presumably were formed. Combining the results on quasar mass limits by McLure & Dunlop (2004) with the results of Ferrarese (2002) (Fig. 5 and eq. 6 in her paper) we can estimate that the masses of the dark matter host halos of the local quasars should have been around \( 10^{12} \) to \( 10^{13} M_\odot \). These mass limits are compatible also with the result by Croom et al. (2005). Moreover, the results by Croom et al. (2005) suggest that the mass of the dark matter halo of a quasar is more or less independent of the redshift. This means that the present-day host dark matter halos of the nearby quasars should have the same mass range \( 10^{12} - 10^{13} M_\odot \).

Using simulations, Gao et al. (2005) showed that on large scales dark matter halo clustering depends on the age of the halo. They concluded that halos of given mass that assembled at high redshift are substantially more strongly clustered than halos of the same mass that assembled recently. The ‘youngest’ 10 per cent of halos are more than five times more strongly correlated than the ‘youngest’ 10 per cent. Harker et al. (2006) studied the environmental dependence of halo formation times. They concluded that halos of a given mass in denser regions formed at high redshifts than those in less dense regions. Maulbetsch et al. (2007) estimate that halos of \( \sim 10^{13} M_\odot \) assemble \( \sim 1.5 \text{Gyr} \) earlier in the high density regions than in the low density regions. Using the Millennium simulation and arguments that link the formation of the dark matter halos to the SBHs and to the formation of early quasars, Springel et al. (2005) also showed that the first quasars end up today as central galaxies in rich clusters. As a result, nearby quasars in low density environments should be younger than quasars in high density environments.

Observationally the clustering of high redshift quasars in the Sloan Digital Sky Survey has been studied by Shen et al. (2007). Their results indicate increasing clustering for high redshift quasars with redshift. Using the 2dFQSO Redshift Survey (2QZ) Croom et al. (2005) showed that quasar clustering increases with redshift. This suggests that earlier quasars were located in higher density environments than the recent ones, and high-redshift quasars can be used as beacons to search for high-density regions (Coldwell & Lambas 2006). Our results of the location of the nearby quasars agree with these observations.

An interesting question is also what is the relation between dark matter halos and their environment with the observed redshift distribution of the number of quasars per unit volume. This distribution for the quasar main population reaches a maximum
around \( z \approx 2 - 3 \) both in X-ray selected and optically selected surveys (Silverman et al. 2005).

Maulbetsch et al. (2007) address the problem how to explain the observed dependencies of galaxies on the environment (the morphology–density relation) with the mass assembly history of dark matter halos. They show that aggregation of mass to the dark matter halos via halo mergers and mass accumulation has a strong dependence on the environment and redshift. While halos in low density environments grow mainly by mass accumulation, in high density environments halo mergers are the dominant aggregation procedure. The latter one is mainly determined by the properties of the subhalo population and the survival of subhalos in the main dark matter halo. The mass fraction accumulated by mergers is a function of redshift and it decreases towards \( z = 0 \).

This concerns both the low and high density environments, but the decrease is steeper in low density regions. At the same time, filaments the halo evolution is suppressed compared to the core halo mergers. In less dense regions of the superclusters rich galaxy interactions.

Finally, for supercluster scales, numerical simulations by Einasto et al. (2005) showed that in voids the dynamical evolution of halos is very slow and finally stops, while in supercluster regions the dynamical evolution continues until the present day. In superclusters, rich clusters in the core regions form first via halo mergers. In less dense regions of the superclusters and rich filaments the halo evolution is suppressed compared to the core regions.

Thus it is not a far-fetched idea that dark matter halos, evolution of the mass aggregation rate and its dependence on environment on all scales play an important role in quasar evolution and their observed redshift distribution. The triggering mechanisms, which influence aggregation onto black holes, may have been suppressed due to environmental reasons, which are also related to the evolution of superclusters. Of course, local astrophysical processes related to baryonic matter must explain the observed properties of quasars in detail.

Taking into account halo formation times and merger rates as a function of the halo mass and halo environment, also on supercluster scales, together with the estimated quasar duty-cycle, it should be possible to generate quasars in cosmological simulations, and to compare the results with the observed quasar distribution. We are planning to do this in our forthcoming paper.

### 5. Conclusions

We have studied the environments of quasars in the SDSS on different scales. Our main results can be summarized as follows:

(i) At the distances from 2 to 20 h\(^{-1}\)Mpc from quasars the number density of galaxies is lower than the density at the same distances from galaxies. This effect is particularly strong for the brightest galaxies.

(ii) The groups of galaxies that have a quasar closer than 2 h\(^{-1}\)Mpc are poorer and less luminous than all the groups in average. Also, groups that consist of four or more galaxies have lower richnesses and luminosities if there is a quasar closer than 10 h\(^{-1}\)Mpc.

(iii) The groups of galaxies that have a quasar neighbour at a 10 to 15 Mpc distance are richer and more luminous than the groups in average. The same result can also be seen if we examine the rich groups only.

(iv) Quasars avoid the densest regions in the (luminosity) density field, which correspond to rich supercluster cores.

Nearby quasars are located in the outskirts of superclusters or in filaments connecting them. Quasar evolution may be related to these largest density enhancements in the Universe.
