Case Report

Page Kidney Phenomenon following Kidney Graft Biopsy

Introduction

Percutaneous renal allograft biopsy is commonly performed as a protocol or diagnostic biopsy after kidney transplantation to detect rejection, recurrence of kidney disease, infection and calcineurin inhibitor (CNI) nephrotoxicity [1,2]. It is generally considered as a safe procedure under ultrasound guidance. However, some complications associated with this procedure can occur. Most common complications are minor and can be managed conservatively. Major complications can occur in about 1% of cases [3,4], which may require blood transfusion, interventional procedure or even surgical exploration. Page kidney phenomenon is one of the rare but serious complications, in which the renal parenchyma is tamponade and its perfusion is compromised as a result of haematoma formation under the renal capsule. This will lead to deterioration in kidney function and graft loss if the diagnosis and management are delayed [5]. Therefore, early recognition of page kidney phenomenon is crucial as prompt evacuation of the haematoma can prevent graft loss and allow complete recovery of renal function [6]. Here we reported two cases of page phenomenon after kidney graft biopsy in our institution. The literatures were also reviewed.

Case 1

A 62-year-old lady with end stage kidney disease due to Type 2 Diabetes underwent second renal transplant. On day 4 post transplantation, she developed antibody mediated rejection and was treated per protocol. A repeat kidney graft biopsy was performed 2 months later. There was no immediate post biopsy complication and her blood pressure remained stable at 140/80 mmHg during the observation period. Her vital signs was stable as well for six hours during the observation. She had no haematuria and thus she was discharged home as per the protocol of kidney graft biopsy. Ten days later, she presented to the emergency department with pain over transplanted kidney, nausea and vomiting. On examination, she looked stable and had a blood pressure of 138/86 mmHg. There was tenderness over the kidney graft. Her haemoglobin was 103g/L compared to 107g/L on the day of her last kidney biopsy, creatinine was elevated to 334 μmol/L from 200 μmol/L. Doppler ultrasound showed a haematoma in the interpolar region of the transplanted kidney. There was no vascular flow demonstrated within this area. The vascular waveforms were abnormal with absence of diastolic flow in the upper and lower pole of the transplanted kidney. The resistance index was increased to 1.2 (Figures 1,2). CT of the abdomen revealed a
subcapsular haematoma in the transplanted kidney (Figure 3). The diagnosis was confirmed as page kidney phenomenon. The patient underwent urgent surgical exploration and evacuation of the subcapsular haematoma of the kidney. There was no active bleeding identified during. The intraoperative Doppler US showed some recovery of kidney perfusion. However, the kidney graft function continued to deteriorate postoperatively. On day 1 post operation, Doppler ultrasound demonstrated normalization of vascular traces in upper and lower pole of kidney graft, but no flow could be obtained in the inter polar region. On day 2 post–operation, renal nuclear perfusion scan showed absence of perfusion and function of the kidney graft. The decision was made to remove the kidney graft. Histopathology confirmed that the kidney graft was non-viable with extensive haemorrhagic infarction involving over 90% of the renal parenchyma.

Case 2

A 58-year-old lady underwent renal transplantation for end-stage renal failure secondary to polycystic kidney disease. Her creatinine was 97 umol/L on discharge. She underwent protocol biopsy. There was no immediate complication and her blood pressure was 130/60 mmHg after biopsy. During the observation period post biopsy, she subsequently developed macroscopic haematuria and worsening pain over the kidney graft. She then became oliguric six hours post biopsy and her blood pressure increased to 160/100 mmHg. On repeat blood test, serum creatinine was elevated to 182 umol/L from 98 umol/L prior to biopsy and her haemoglobin level was stable. An urgent Doppler ultrasound was performed. There was a subcapsular haematoma in the inferior pole of the transplanted kidney with a high resistivity index of 1 in the interlobar arteries of the kidney parenchyma. There was also a reversal diastolic blood flow (Figures 4,5). The decision was made for urgent exploration and evacuation of the subcapsular haematoma. During surgery a subcapsular haemotoma was seen. Following evacuation of haematoma, an active bleeder was identified from the biopsy site at the lower pole of the kidney. The haemostasis was achieved by over sewing the bleeder with a 3/0 Vicryal suture.

The patient recovered well with good urine output post-surgery. On repeat Doppler US, there was a normalised parenchymal blood flow in the transplanted kidney (Figure 6). However, the kidney graft function had continuously worsened over the next few days with a peak Cr level of 744 μmol/L on day 6 post surgery. Fortunately, the Cr level started to improve over the next few weeks. It was at 297 μmol/L one month post-surgery and slowly recovered to a baseline of 120 μmol/L. The kidney graft function was stable over the 3 years follow up.

Discussion

Percutaneous renal biopsy has been increasingly used as a protocol biopsy after kidney transplantation. It is also commonly performed to diagnose the underlying pathology when the renal function deteriorates. However, it is associated with some potential complications such as haematuria, urinary tract obstruction by clots, formation of pseudoaneurysm and/or arteriovenous fistula and peri-graft or subcapsular haematoma. The incidence of the complications ranged from 0.7% to 30% [6], whereas the major complication requiring interventional procedure was about 1% [5].

The Page kidney phenomenon was first described by Dr. Page in an experimental model in 1939 [7]. In the experiment, cellophane was wrapped around a native kidney leading to the constriction in renal parenchyma and hypertension [7]. In the context of kidney transplantation, Page kidney phenomenon can occur spontaneously after kidney transplantation [8,9], after percutaneous kidney graft biopsy [5,10–12], or after trauma to the allograft [13]. It can also occur in a native kidney [14]. There is a paucity of reports describing subcapsular haematoma following kidney graft biopsy [5,8,10–12]. It has the same effect as demonstrated in the Page kidney experiment. The haematoma compresses on the renal parenchyma as a
tamponade effect and thus reduces the kidney perfusion. Wanic-Kossowska et al [15], reported 3 cases of Page kidney phenomenon in consecutive 800 renal biopsies; two of cases developed subcapsular haematoma and one developed a huge peri-kidney haematoma. In addition, Chung et al [12]. reported 4 cases of Page kidney phenomenon in 518 renal transplant biopsies. The page kidney phenomenon may develop almost immediately after percutaneous renal biopsy. However, it could have delay presentation sometimes such as 10 days following biopsy [11], as in our case 1.

In our experience, Doppler US is a useful modality for prompt diagnosis in the setting of percutaneous kidney graft biopsy. Urgent investigation should be performed with Doppler US of the kidney graft with reduction in urine output is an alert for suspicion of Page kidney phenomenon after percutaneous biopsy. In our opinion, an acute pain over the graft with reduction in urine output is an alert for suspicion of Page kidney phenomenon when subject to percutaneous kidney graft biopsy. Doppler US is an acute useful modality for prompt diagnosis. The early recognition of Page kidney phenomenon and prompt surgical intervention is fundamental to prevent the graft loss.
