Received July 11, 2012; accepted October 17, 2012

Cigarette smoking is the leading cause of lung cancer and chronic obstructive pulmonary disease, yet there is little mechanistic information available in the literature. To improve this, laboratory models for cigarette mainstream smoke (MS) inhalation–induced chronic disease development are needed. The current study investigated the effects of exposing male A/J mice to MS (6h/day, 5 days/week at 150 and 300 mg total particulate matter per cubic meter) for 2.5, 5, 10, and 18 months in selected combinations with postinhalation periods of 0, 4, 8, and 13 months. Histopathological examination of step-serial sections of the lungs revealed nodular hyperplasia of the alveolar epithelium and bronchioalveolar adenoma and adenocarcinoma. At 18 months, lung tumors were found to be enhanced concentration dependently (up to threefold beyond sham exposure), irrespective of whether MS inhalation had been performed for the complete study duration or was interrupted after 5 or 10 months and followed by postinhalation periods. Morphometric analysis revealed an increase in the extent of emphysematous changes after 5 months of MS inhalation, which did not significantly change over the following 13 months of study duration, irrespective of whether MS exposure was continued or not. These changes were found to be accompanied by a complex pattern of transient and sustained pulmonary inflammatory changes that may contribute to the observed pathologies. Data from this study suggest that the A/J mouse model holds considerable promise as a relevant model for investigating smoking-related emphysema and adenocarcinoma development.

Key Words: lung tumorigenesis; pulmonary emphysema; lung inflammation; cigarette mainstream smoke; inhalation; A/J mice.

Although the causal relationship of smoking and the development of serious diseases such as lung cancer (LC), chronic obstructive pulmonary disease (COPD), and cardiovascular disease has been established (U.S. Department of Health and Human Services, 2004), we are still missing a clear understanding of the etiology and mechanisms leading to these smoking-induced pathologies (U.S. Department of Health and Human Services, 2010). Such understanding could be the basis for developing biomarkers for early diagnosis of these diseases, chemopreventive means, and targeted therapies. Apart from clinical and molecular epidemiological studies, in vitro and in vivo models are needed to improve the mechanistic understanding of these diseases. Such models may also support the development and evaluation of modified tobacco products with potentially reduced risk for those who continue smoking (Haussmann, 2007; U.S. Institute of Medicine, 2012). To date, however, there is no generally accepted laboratory animal bioassay for LC induced by chronic cigarette mainstream smoke (MS) inhalation. In the past, attempts to establish such models were generally unsuccessful (reviewed by Coggins [2010]), for reasons not fully understood. More recently, however, some chronic MS inhalation studies with mice or rats that followed specific design considerations were positive in demonstrating lung tumor formation (Balansky et al., 2007; Curtin et al., 2004; Gordon and Bosland, 2009; Hutt et al., 2005; Mauderly et al., 2004; Stinn et al., 2010).

The most promising rodent strain studied so far for investigating smoke-induced LC seems to be the A/J mouse because of its high susceptibility to spontaneous and chemically induced LC development (Manenti and Dragani, 2005) and its reproducible positive LC response to inhalation of a mixture of cigarette sidestream and MS used as an environmental tobacco smoke surrogate (ETSS) (Coggins, 2010; Witschi, 2005). The high LC susceptibility has been associated with the presence of pulmonary adenoma susceptibility (PAS) loci in the A/J genome, in particular PAS1 (Manenti and Dragani, 2005), and an increased transcription rate of Kras, particularly if mutated (To et al., 2006). Both PAS1 and Kras have also been reported to induce inflammatory processes (Maria et al., 2003; Wislez et al., 2006). Inflammation has been considered to be involved in tumorigenesis (Walser et al., 2008) although the
causal role of specific inflammatory processes in the various steps of tumorigenesis remains to be elucidated. Inflammatory processes are also involved in other smoking-related diseases, such as COPD (Cosio et al., 2009), and a mechanistic link between COPD and LC via such inflammatory processes has been discussed (Adcock et al., 2011; Houghton et al., 2008). Pulmonary emphysema, a characteristic feature of COPD, has been described in several laboratories for this mouse strain after approximately 6 months of MS inhalation (Braber et al., 2011; Foronjy et al., 2005; Guerassimov et al., 2004; March et al., 2005; Nadziejko et al., 2007). Therefore, the A/J mouse may be particularly useful to study the development of emphysema and LC in parallel upon chronic MS inhalation.

Previous MS inhalation studies with A/J mice were positive for lung tumors in some laboratories but not in others (Stinn et al., 2010); this may be due to differences in study design parameters such as sufficiently large group sizes or the exposure schedule. All positive studies so far have adhered to a schedule involving several months of MS inhalation followed by a postinhalation period without exposure for several months, which has been adapted from the positive lung tumorigenesis studies with ETSS (Witschi, 2005). This differs from the human situation, where the relative risk of acquiring LC decreases with time after smoking cessation (U.S. Department of Health and Human Services, 1997). The apparently paradoxical need for a postinhalation period to express the tumorigenic potential of prior smoke inhalation in A/J mice has generated debate on the relevance of this model for the human disease and needs to be further evaluated as a prerequisite for broader acceptance of this model. Elucidating a potential effect of a postinhalation period on the development of MS-induced emphysema would also be useful in judging the biological relevance of this model, e.g., by excluding reversibility that could hypothetically be due to a smoke exposure–related body weight effect such as after fasting (Massaro et al., 2004). In humans, smoking-induced COPD is considered to be irreversible, and smoking cessation may only interrupt the progression of the disease (U.S. Department of Health and Human Services, 2004).

Our long-term aim has been to develop and validate suitable nonclinical models for smoking-related diseases such as pulmonary cancer and emphysema. A generally acceptable disease model for mechanistic and applied purposes should use chronic MS inhalation as the major causative agent and exposure route relevant for the human disease, follow a concentration–response relationship, work without the need for a postinhalation period, be qualitatively and quantitatively reproducible, and demonstrate mechanistic features that have also been considered relevant in human disease pathogenesis. Several of these design parameters were evaluated in this study, which involved male A/J mice exposed to MS inhalation for 2.5 to 18 months at two concentrations in combination with postinhalation periods of up to 13 months. Lungs were investigated for the presence of emphysema and lung tumors and potentially relevant mechanistic endpoints, i.e., inflammatory effects and Kras mutations.

MATERIALS AND METHODS

General study design. The investigation of lung tumorigenesis was the major objective of this study, which featured a schedule of MS inhalation and postinhalation periods with several dissection time points for the endpoints investigated as outlined in Figure 1 (not all endpoints assessed at all time points or concentration levels). Major design features of this whole-body MS inhalation, such as smoking machine and exposure conditions, were as previously described (Stinn et al., 2010). Total particulate matter (TPM) concentrations in this study were slightly higher, i.e., 150 mg/m³ (MS-150) and 300 mg/m³ (MS-300). MS was generated from the Reference Cigarette 2R4F, which was obtained from the University of Kentucky (Lexington, KY), in basic conformity with international standards for cigarette conditioning and machine smoking (International Organization for Standardization, 1991, 2000). A sham-exposed control group was treated the same way but exposed to fresh air instead of MS. Analytical characterization of the MS was performed as described (Stinn et al., 2005, 2010).

The study was approved in accordance with the Belgium Law on Animal Protection. The study was performed in an American Association for Laboratory Animal Care (AALAS)–accredited facility (Association for the Assessment and Accreditation of Laboratory Animal Care International, 1991), where care and use of the mice were in accordance with the AALAS Policy on the Human Care and Use of Laboratory Animals (http://www.aalas.org).

Experimental animals and inhalation exposure. Male A/J mice, bred under specified pathogen-free conditions (The Jackson Laboratory, Bar Harbor, Maine), were obtained through Charles River France (L’Arbresle, France). At arrival, the age of the mice was between 6 and 10 weeks. The health of the mice was checked serologically and histopathologically. Within 1 week after arrival, the mice were individually identified with subcutaneous transponders (Bio Medic Data Systems Inc., Seaford, DE). The acclimatization period was 3.5 weeks. In total, 388 mice were randomly allocated to sham and MS-300 groups, respectively, and 264 mice to the MS-150 group. Most of the mice were used for investigating tumor development; up to 10 mice/group were allocated to mechanistic endpoints. Mean body weight per group at the start of exposure was approximately 23 g, with a relative SD of less than 10%. The mice were fed irradiated Harlan Teklad 2014 diet (Harlan, Blackthorn, UK). Food was removed during the daily exposure periods. Filtered tap water was available at all times. Irradiated softwood granulate bedding material, type Lignocel BK8/15 (Harlan, Horst, NL), was used. The position of the cages in the exposure chambers was rotated twice weekly. In each exposure chamber, there were at least six air changes per hour, and the equivalent flow rate was at least 99 l/min, resulting in a mean aerosol age of ≤ 6 min in the middle of the exposure chamber. Mean temperature in the exposure chambers was approximately 21°C with relative SDs of less than 5%. Relative humidity in the sham exposure chamber was 53.5 ± 4.9% (mean ± SD) during exposure. The exposure period started with adaptation periods of 2, 3, 4, and 5 h/day for 3 days each. Standard exposure was for 6 h/d, 5 d/week.

Biological endpoints. In-life observations and determinations, necropsy, organ weights, and lung histopathology were performed as previously described (Stinn et al., 2010), but no macroscopic evaluation and no specific collection of pulmonary nodules was conducted (except for Kras analysis). Lungs were inflated for 1 min with Tellyesnicky’s solution at a constant hydrostatic pressure of 15 cm water column, fixed for 1 day, and thereafter kept in 70% ethanol. Serial sectioning of the lungs was performed at 300-µm steps. Nonneoplastic changes were examined at one cross section along the main bronchus of the left lung. Proliferative pulmonary lesions were diagnosed in line with published criteria (Dungworth et al., 2001). Incidence and multiplicity (average number of tumors per mouse) were determined. Mice that died spontaneously or were killed in a moribund state were necropsied and investigated histopathologically.

In order to quantify emphysematous changes, three morphometric analyses were performed on up to 10 mice per group: mean chord length, destructive index, and the number of bronchiolar attachments of alveoli (Thurlbeck and Churg, 1995). Morphometric measurements were executed using approximately
30% of one representative cross section of the left lung lobe per mouse including the left main stem bronchus. Blinded measurement was applied throughout all evaluations on randomly selected image fields using digital imaging (Visiopharm, Horsholm, Denmark). Mean chord length was determined using isotropic uniform random (IUR) lines that passed through the tissue. The chord length was measured by marking the points where the IUR line intersected the surface of the alveoli. Bronchiolar attachments of alveolar walls per unit bronchiolar basement membrane length were determined per field of view by dividing the number of attachments by the length of the perimeter of the bronchiolus. The destructive index was determined by point counting. A point grid was placed over each of the fields of view, and counts were taken of the number of points that fell on destroyed alveoli (representing an emphysematous damage) and points that fell on normal alveoli. The number of points that fell on destroyed alveoli divided by the total number of points is the destructive index. An overestimation of destroyed structures cannot be excluded in this analysis and would increase the resulting destructive index but diminish any MS-related emphysematous effect.

Inflammatory cells and mediators were investigated in bronchoalveolar lavage fluid (BALF) (Fig. 1), which was obtained from up to 10 mice per group similarly to a previously described procedure in rats (Friedrichs et al., 2006). Mice used for inflammatory parameters in BALF were also used for the examination of proliferative pulmonary lesions, but not for the morphometric examination of emphysema. Lungs were lavaged with 1 ml of Ca²⁺- and Mg²⁺-free PBS using a syringe, and the BALF was centrifuged to obtain cell-free BALF supernatant. Lungs were then lavaged with four more consecutive cycles of filling and emptying with 1 ml of Ca²⁺- and Mg²⁺-free PBS containing 0.3% bovine serum albumin to optimize cell recovery. The cell-free supernatant fraction of the first cycle was used for the determination of inflammatory mediators using a multiplex ELISA (Endogen SearchLight Multiplex Assay; Endogen, Woburn, MA), which allows the simultaneous quantitative determination of up to 16 mediators. All cell-containing BALF fractions were combined. BALF cells were fixed in 2% formaldehyde and differentiated by flow cytometry using anti-Ly-6G (clone 1A8, FITC-labeled) and anti-F4/80 (clone Cl:A3-1, APC-labeled) after blocking FcIII/II receptors with anti-mouse CD16/CD32 (clone 2.4G2, unlabeled) (all BD Biosciences, Heidelberg, Germany), followed by nucleic acid counterstaining of saponin-permeabilized cells using propidium iodide. For the further BALF lymphocyte differentiation, the following additional antibodies were used for monocytes/macrophages (clone BM8, FITC-labeled; Dianova, Hamburg, Germany), CD4 (clone RM4-5, PerCP-labeled), CD8 (clone 53–6.7, PE-Cy7-labeled), B cells as CD45R/B220 (clone RA3-6B2, APC-Cy7-labeled, all BD Biosciences), and CD94 (clone 18d3; Alexa Fluor 647-labeled; AbD-Serotec, Duesseldorf, Germany). BALF alveolar macrophage activation markers were analyzed by flow cytometry with antibodies against CD11b (clone M1/70, APC-Cy7-labeled), CD86 (clone GL1, biotin-labeled), CD14 (clone rmC5-3, PE-labeled; all BD Biosciences), and MHCII (haplotype I-Ak,s, clone OX-6, Alexa Fluor 647-labeled; AbD-Serotec), followed by staining with streptavidin (PE-Cy7-labeled). A second aliquot was stained with a cocktail of corresponding rat isotype controls. For each fluorescence parameter, the median fluorescence intensity of the isotype-stained sample aliquot was subtracted from that of the antibody-stained aliquot.

Bronchial lymph node lymphocytes were collected and analyzed by flow cytometry in a similar manner to a previously described procedure in rats (Friedrichs et al., 2006). The lymphocytes were immunostained for CD45 (clone 30-F11, PerCP-labeled), CD4 (clone 129.19, FITC-labeled; both BD Biosciences), CD8, and CD45R/B220. To assess the activation status of CD4 and CD8 T cells, lymphocytes were immunostained for CD25 (clone PC61, APC-labeled) and CD69 (clone H1.2F3, PE-labeled, first aliquot) and for
CD44 (clone IM7, PE-labeled) and CD62L (clone MEL-14, APC-labeled, second aliquot; all BD Biosciences) and analyzed by flow cytometry.

To investigate mutations in the Kras gene, DNA was prepared from freshly frozen tumor tissue and, in order to increase the number of tissues investigated, from formalin-fixed, paraffin-embedded tumor tissue. Cryosections of 10 µm were dehydrated in ice-cold 70% ethanol for 2 min. The paraffin sections were deparaffinized with xylene substitute medium and rehydrated with 100% and 70% ethanol. All sections were stained with Cresyl Violet (Sigma, Taufkirchen, Germany). Different areas of tumor tissue were selected that contained approximately 5000 cells. Specific samples were isolated by laser capture microdissection and pressure catapulting using the PALM Microbeam instrument (Zeiss, Oberkochen, Germany). Genomic DNA was isolated from the tumor tissue samples using the QIAamp DNA Micro-Kit (Qiagen, Hilden, Germany) according to manufacturer instructions. Amplification and sequencing were performed as previously described (Stinn et al., 2005). Due to the relatively small number of samples investigated for each type of preparation, the results were combined.

**Statistical evaluation.** For continuous data, the arithmetic mean and the SE are generally given as descriptive statistics; however, for chemical-analytical or physical data describing the test atmosphere, the SD was calculated. Chemical-analytical values below the quantitation limit (QL) were presented as < QL. Particle size distribution was calculated by linear regression analysis after probit transformation of the cumulative frequencies and logarithmic transformation of the aerodynamic diameter values. Data on inflammatory mediators in BALF and activation markers on alveolar macrophages were not normally distributed and are given by their median and 25 and 75% quartiles. Continuous or physical data describing the test atmosphere, the SD was calculated. Chemical-analytical values below the quantitation limit (QL) were presented as < QL. Particle size distribution was calculated by linear regression analysis after probit transformation of the cumulative frequencies and logarithmic transformation of the aerodynamic diameter values. Data on inflammatory mediators in BALF and activation markers on alveolar macrophages were not normally distributed and are given by their median and 25 and 75% quartiles. Continuous data, such as organ weights, blood corticosterone levels, morphometric data, and tumor multiplicity, were statistically evaluated using a one-way ANOVA followed by a Tukey test (Zar, 1984). Inflammatory data were transformed by ranking prior to ANOVA. Histopathological ordinal data were analyzed using an overall Cochran-Mantel-Haenszel (CMH) test followed by a pairwise CMH in the case of overall statistical significance (Mantel and Haenszel, 1959). All tests were considered statistically significant at p < 0.05. No correction for multiple testing was performed.

**RESULTS**

**Inhalation Exposure**

The MS test atmospheres were reproducibly generated throughout the 18-month inhalation period (Table 1). The mass median aerodynamic diameter of the smoke particles ranged from 0.60 to 0.75 µm (largest geometrical SD: 1.72), making the aerosol respirable for the mice. Percent carboxyhemoglobin proportions of 0.4 ± 0.1, 17.2 ± 0.6, and 31.4 ± 1.4 (mean ± SE; N = 8 per group at four time points during the study) for the sham, MS-150, and MS-300 groups, respectively, correlated with the MS carbon monoxide concentrations of the test atmospheres.

**In-Life Observations and Determinations**

The number of mice that were declared moribund or that died spontaneously was higher in the sham group (26%) than in the MS-150 (18%) and the MS-300 groups (16%). Several mice were declared moribund (7.7, 5.7, and 2.8% in the sham, MS-150, and MS-300 groups, respectively) because they developed a swelling that was identified as a neoplastic lesion, identical in histomorphological appearance to a rhabdomyosarcoma. The swelling was usually located in the skeletal muscle of the hind limbs or appeared as a protrusion in the lower abdominal cavity. Thus, survival was lowest in the sham group (statistically significantly different from the MS groups), reaching 50% by study day 521 (Fig. 2).

Body weights in the sham group initially increased and remained steady within a range of 28.5 to 29.4 g between study days 165 and 431, decreasing to approximately 27.5 g by the end of the 18-month study period. The mice in the MS groups lost weight in the first 4 weeks to approximately 85% of the sham group and afterwards gained weight reaching levels of approximately 90% (MS-150) to 85% (MS-300) of the sham group. Mice that changed from MS inhalation to the postinhalation exposure phase of the study regained weight within a few weeks to the level of the sham group. During inhalation periods, food consumption paralleled the effects on body weight development, with weekly consumptions of 27.8 ± 0.4, 26.7 ± 0.3, and 25.0 ± 0.4 g/mouse (mean ± SE) for the sham, MS-150, and MS-300 groups, respectively. During postinhalation periods, mice in the MS groups increased their food consumption back to the level of the sham group.

### Table 1

| Parameter (mg/m³) | N   | Sham | Mean ± SD | MS-150 | Mean ± SD | MS-300 | Mean ± SD |
|------------------|-----|------|-----------|--------|-----------|--------|-----------|
| TPM              | > 384 | < 1.6 | 153 ± 8   | 298 ± 15 |
| Carbon monoxide  | > 382 | < 4.5 | 210 ± 17  | 374 ± 19 |
| Nicotine         | > 20  | < 0.03 | 5.9 ± 0.8 | 13.0 ± 2.0 |
| Formaldehyde     | 26   | —    | 0.18 ± 0.05 | 0.30 ± 0.04 |
| Acetaldehyde     | 26   | —    | 11.6 ± 1.0 | 22.4 ± 1.1 |
| Acrolein         | 26   | —    | 1.16 ± 0.10 | 2.26 ± 0.11 |

*Note.* Averaged over 18 months of MS generation. ❌, not scheduled.

*MS-150 and MS-300: MS at target concentrations of 150 and 300 mg TPM/m³, respectively.*

![FIG. 2. Kaplan-Meyer survival curves for sham, MS-150 (MS at 150 mg TPM/m³), and MS-300 groups. No differentiation was made for continuous 18-month or shorter MS exposure periods followed by postinhalation periods. Asterisks denote statistical significance compared with the sham group.](https://academic.oup.com/toxsci/article-abstract/131/2/596/1642618/1)
MACROPHAGES showed a drastic decrease due to MS inhalation, which is a consequence of the marked increases in neutrophils and lymphocytes. Within the limits of this analysis, the progressive recovery of the relative number of macrophages may also be related to the decreasing proportion of neutrophils in the total cell number.

In order to test for the potential activation of alveolar macrophages by MS inhalation, the expression of typical activation markers was analyzed, i.e., CD11b (Mac-1 α-chain), CD86 (costimulatory molecule B7.2), major histocompatibility complex class II (MHCII), and CD14 (LPS receptor), at exposure regimens 10 + 0, 10 + 4, and 18 + 0 months. These markers were slightly higher after MS inhalation but reversed after 4 months of postinhalation (Supplementary table S1).

An attempt was made to differentiate various lymphocyte subtypes in BALF. Such differentiation was only possible in a few sham mice due to the low number of total lymphocytes harvested. In the MS groups, enough cells were available, and a differentiation was performed for exposure regimens 10 + 0 and 10 + 4 months. The relative proportions of CD4, CD8, NK, and B cells did not suggest any smoking effect (Supplementary table S2).

A more comprehensive differentiation was performed on those lymphocytes harvested from the bronchial lymph nodes draining the alveolar tissue, from which enough cells were available. No consistent difference was observed in the proportions of CD4, CD8, and B cells between MS and sham groups, independent of the MS concentration or exposure regimen (Supplementary table S3). In addition, no consistent effect on lymphocyte activation markers CD69, CD25, CD44, and CD62L was observed on either CD4 or CD8 cells (Supplementary tables S4 and S5).

MS inhalation resulted in a statistically significant increase in proinflammatory cytokines IL-1α, IL-6, IL-12p40, IFN-γ, and TNF-α in BALF, in general, in a concentration-dependent manner (Supplementary table S6). The most pronounced effect was observed at 10 months. With the exception of IL-6, there was a partial recovery of these inflammatory changes during the 4-month postinhalation periods, which was most obvious in the low concentration group (MS-150). IL-1β, which was only determined during the 5-month MS inhalation period, did not change (data not shown). The chemokines KC, MCP-1, MCP-5, MIP-1α, MIP-2, and RANTES in BALF were statistically significantly increased as a consequence of MS inhalation (Supplementary table S6). In the majority of cases, the response was concentration dependent. A progressive effect with increasing MS inhalation periods was observed for MCP-1 and MIP-1α in the MS-300 group. After exposure at the high MS concentration for 5 or 10 months, there was no reversal of the chemokine responses during the 4-month postinhalation period, except for MCP-5; however, after exposure to the low MS concentration, a reversal was generally observed. Matrix metalloproteinases MMP-2, MMP-3, and MMP-9 increased in a concentration-dependent manner with no particular progression with increasing MS inhalation period observable within the limits of variation of the data. These effects showed partial reversal during the postinhalation periods.
Thus, there was a broad picture of concentration-dependent inflammatory effects, many of which seemed to progress with increasing MS inhalation period and began to reverse upon postinhalation. Although the lymphocyte population at large increased upon MS inhalation, no change in subpopulation composition or activation status in BALF or lymph node lymphocytes was found.

Organ Weights

Lungs were weighed with trachea and larynx attached. The respective weights increased with MS concentration (Supplementary fig. S1). A trend for increased weights of lungs with trachea and larynx was still observable at the end of the postinhalation periods of various durations, even after 13 months of postinhalation following the 5-month inhalation period. Spleen weights tended to be lower and adrenal weights tended to be higher after MS inhalation; however, in general these data did not change in a statistically significant manner (data not shown).

Nonneoplastic Pulmonary Histopathology

A chronic inflammatory reaction in the lung tissue was also recognized histopathologically. It was characterized

| Parameter                  | Exposurea | Descriptorb | 5 + 0 | 5 + 4 | 5 + 8 | 5 + 13 | 10 + 0 | 10 + 4 | 10 + 8 | 18 + 0 |

cData obtained from lavages at regimens 0 and 2.5 + 0 months could not be integrated due to changes in lavaging techniques.
by a multifocal mild to moderate histiocytic infiltration with unpigmented macrophages and macrophages with an intracytoplasmatic brownish to yellow pigmentation. The pigmented macrophages were partly arranged in small intra-alveolar clusters best described as pigmented macrophage nests (Fig. 5). These nests were associated with focal hyperplasia/hypertrophy of pneumocytes. These effects persisted for the most part throughout the postinhalation periods. In addition, a mild multifocal intra-alveolar accumulation of neutrophilic granulocytes and lymphocytes, a mild lymphocytic perivascular cell infiltration, and a mild to moderate hyperplasia of the bronchus-associated lymphoid tissue were observed mainly in the MS groups. Although these inflammatory effects increased slightly from 5 to 10 months of MS inhalation, there was no further increase seen at 18 months. At the end of the postinhalation periods, inflammatory effects were still more pronounced in the groups with prior MS inhalation than in the sham group. This is indicative of, at best, partial recovery.
of MS effects and is in line with observations on cellular and humoral inflammatory markers assessed in BALF.

Multifocal alveolar emphysematous changes were seen in the lungs of nearly all mice. These changes were quantitatively evaluated at the cross section along the main bronchus of the left lung by three morphometric methods. The results obtained by the three methods, i.e., mean chord length, destructive index, and bronchiolar attachments, are similar but not identical (Table 3 and Fig. 6). There was no age-dependent development for the mean chord length and the destructive index, but the number of bronchiolar attachments tended to decrease with age. MS exposure resulted in increased emphysema, which was already observed after 2.5 months of MS inhalation, although only for the destructive index. In general, the MS effect was not very pronounced but achieved maximal changes of 20, 40, and 50% beyond the sham group for mean chord length, destructive index, and number of bronchiolar attachments, respectively. At the end of the 18-month inhalation period, the emphysematous effect was statistically significant for all three morphometric endpoints for both MS concentration groups in a roughly concentration-dependent manner. There was little progress or regression in the extent of the emphysematous effect over the course of the study, irrespective of whether MS exposure was continued or not (Fig. 6). For the destructive index and the number of bronchiolar attachments, there was a trend to less pronounced effects upon termination of MS exposure after 5 months of inhalation, but not after 10 months of inhalation.

| Bronchiolar attachments (1/mm)| Sham     | Mean       |

Test: Symbols * and # represent statistically significant difference to sham- or MS-150–exposed mice, respectively.

### Proliferative Pulmonary Lesions

The incidence and multiplicity of bronchioloalveolar proliferative findings increased with study duration and thus with age (Table 4). In sham group, the level of nodular alveolar hyperplasia remained relatively low throughout the entire study. The multiplicity of spontaneous bronchioloalveolar adenoma increased with age until approximately 9 months into the study, at which point it leveled off, whereas bronchioloalveolar carcinomas were first seen at this age and took off thereafter. At 18 months, the majority of tumors in the sham group were carcinomas, whereas there was a balanced ratio of carcinomas to adenomas in the MS groups (Fig. 7), a difference which was statistically significant for both MS groups compared with the sham group. At this point in time, an MS concentration-dependent increase in the multiplicity of the combined pulmonary proliferative lesions (Table 4), both lung tumor types combined (data shown for continuous MS inhalation only, Fig. 7), and the individual lung tumor types was observed, regardless of the MS exposure regimen used, i.e., 5 + 13, 10 + 8, or 18 + 0 months. Most MS-induced findings were statistically significantly different compared with those in the sham group. For the most robust endpoints, i.e., the combined...
proliferative findings or both tumor types combined, a statistically significant difference was also found between the two MS concentrations (Table 4, Fig. 7). For both tumors combined, the multiplicity increased by 2.1- and 2.7-fold after 18 months of MS inhalation at the low and high concentrations, respectively. Directly at the end of the inhalation periods at 5 and 10 months, statistically significant increases in multiplicity were generally not observed; if anything, multiplicities of the two tumor types were lower than those in the sham group (Fig. 8). Thus, tumor multiplicities increased either after 18-month MS inhalation without postinhalation or after shorter periods of MS inhalation followed by postinhalation periods of various durations. The highest multiplicity of proliferative findings was found after an exposure regimen of 10 + 8 months. The proliferative lesions were distributed across the five lung lobes in general accordance with the respective tissue mass (data not shown).

The size of the tumors was estimated by the number of 300-µm sections transected by each individual tumor. In the sham group at the end of the 18-month study period, adenomas transected 3.05 sections on average, whereas carcinomas transected 5.43 sections (Fig. 9), resulting in average sizes of 0.6 to 1.2 mm for adenomas and 1.2 to 1.8 mm for carcinomas. After MS inhalation for 18 months, adenomas and carcinomas were found to be smaller. The same trend was observed for 10 + 8 months (data not shown).

**Kras Mutation**

Tumor samples from mice exposed to MS for 5 or 18 months showed higher mutation rates than those from sham mice (Table 5) although the majority of Kras genes in spontaneous tumors were already mutated. Most mutations were found in codons 12 and 61 with no difference between MS and sham groups. The majority of mutations were G → T transversions. Overall, no shift in Kras mutation pattern was observed as a consequence of MS exposure.

**DISCUSSION**

Chronic MS inhalation for 18 months induced the development of both pulmonary adenoma/adenocarcinoma and emphysematous changes in this A/J mouse model in a concentration-dependent manner. The time course and the reaction to the various inhalation and postinhalation regimens were different for the two chronic disease outcomes. They were accompanied by marked inflammatory reactions, which appeared in patterns of transient and sustained responses to the various inhalation regimens.

Lung tumor multiplicities seen after chronic MS or ETSS inhalation in this and other studies were up to one order of magnitude lower than those seen after the ip application of single chemical carcinogens to A/J mice (Estensen et al., 2004; Pereira et al., 2002; Shimkin and Stoner, 1975; Stinn et al., 2005; Witschi et al., 2005) although smoke inhalation was performed close to maximum tolerated doses (e.g., determined as body weight effect or carboxyhemoglobin proportions in blood in this study). Considering all proliferative findings in this study, the 18-month MS inhalation induced a 2.4-fold increase in multiplicity beyond the sham group. This is practically the same increase that was obtained when using a schedule of 5 + 4 months of inhalation and postinhalation, respectively, in this study (2.5-fold) and in previous MS inhalation studies (2.5- and 2.8-fold) (Curtin et al., 2004; Stinn et al., 2010). Also, following a 6-month ETSS inhalation period with A/J mice, very similar increases were found after 4 or 17 months of postinhalation...

**Note.** The sham-exposed mice for the 5 + 13, 10 + 8, and 18 + 0 months of exposure regimens are the same.

³Pooled analysis of findings in all lung lobes.

¹MS-150 and MS-300: MS at target concentrations of 150 and 300 mg TPM/m³, respectively.

²Test: Symbols * and # represent statistically significant difference to sham-exposed or MS-150–exposed mice, respectively.
A slightly higher increase in the multiplicity of all proliferative findings was only observed in this study after 10 months of MS inhalation and 4 to 8 months of postinhalation (3.8- and 3.0-fold, respectively). Thus, both types of smoke exposure regimens, i.e., long-term smoke inhalation with no postinhalation and shorter term chronic smoke inhalation followed by a postinhalation period, reveal a similar extent of smoke inhalation–induced tumorigenic response in this model. Long-term inhalation is in accordance with the requirements of a regulatory bioassay, whereas a shorter term chronic inhalation followed by a postinhalation period may provide useful data, e.g., in comparative studies when sufficient test material for long-term or lifetime studies is not available.

The A/J mouse is highly susceptible to developing lung tumors, both spontaneous and chemically induced, which has been proposed to be related to an increased transcription rate and a potential sensitivity of the \( K_{ras} \) proto-oncogene for mutation (Chen et al., 1994; To et al., 2006). Because this gene is often found mutated in human adenocarcinomas and is considered an early event (Thunnissen et al., 2012), the A/J mouse may be a useful model for human smoking-related LC. However, significant changes in \( K_{ras} \) mutation patterns in lungs or lung tumors of MS- and ETSS-exposed mice were not found in this study nor in previous studies although there might be a trend toward slightly higher mutation frequencies (Hutt et al., 2005; Stinn et al., 2005; Wang et al., 2005; Witschi et al., 2002). This raises the question of whether smoke in this mouse model acts as an initiator or as a promoter on the basis of an already activated oncogene. So far, it has not been possible to allocate tumors found in smoke-exposed mice to either a spontaneous or a chemically induced origin based on histopathological or molecular biological investigations, which might have been helpful in distinguishing between the promotion of “spontaneous” or newly induced tumors in response to smoke inhalation.

The requirement for a postinhalation period to express a smoke-dependent tumorigenic effect after shorter term chronic inhalation periods was the same for ETSS and MS inhalation studies (this study; Curtin et al., 2004; Stinn et al., 2005, 2010; Witschi, 2005). This was attributed to the triggering of a
tumorigenic process along with a concurrent inhibition of this process during direct smoke exposure. The balance of protumorigenic and inhibitory effects turns positive upon long-term inhalation. In a previous study, the inhibitory effect of direct smoke exposure was attributed, at least in part, to corticosterone, which is increased in high-concentration ETSS and MS inhalation studies (Stinn et al., 2005, 2010). This increase is probably a stress response to the respiratory irritation by smoke exposure and/or an adrenocortical response to nicotine (Cam and Bassett, 1984). Glucocorticoids have been shown to inhibit alveolar epithelial cell proliferation (Droms and Malkinson, 1991) and lung tumorigenesis in mice, which was induced by the application of chemical carcinogens or by ETSS inhalation (Wang et al., 2003; Witschi et al., 2005). The corticosterone response to MS inhalation seemed to weaken in this study with longer MS inhalation periods, and the responsiveness of glucocorticoid-triggered pathways might decline with age, which, taken together, could explain the long-term expression of the lung tumorigenic response in this study without the need for a postinhalation period. These findings could be interpreted as a delay of the smoke-induced tumorigenic process by concomitant smoke exposure. This interpretation is supported by the reduction in tumor size and the lower extent of malignancy in MS-exposed compared with sham-exposed mice. The lower extent of malignancy was also observed after chronic ETSS inhalation (Witschi et al., 2002). In the same way, chronic ETSS inhalation inhibited urethane-induced lung tumorigenesis in A/J mice (Stinn et al., 2005). The observations of a delayed or inhibited tumorigenesis upon concurrent smoke exposure are in line with an increased expression of senescence markers in in vitro and in vivo exposures to MS (Tsujii et al., 2004) and with smoke-induced inhibition of bronchial epithelial repair processes (Wang et al., 2001), which, when unleashed, could potentially promote tumorigenesis. Although the inhibitory effect of glucocorticoids on murine lung tumorigenesis is evident, a similar effect may also be protective in human LC development. This has been suggested by epidemiological studies in smokers undergoing glucocorticoid inhalation therapy as treatment for COPD (Kiri et al., 2009; Parimon et al., 2007).

A transient increase in smoking-related mortality after quitting can be observed in human former smokers (Godtfredsen et al., 2008; Knoke et al., 2008; U.S. Department of Health and Human Services, 1997), a phenomenon that was previously discussed in the context of a need for a postinhalation period to express smoking-induced tumorigenesis in the A/J mouse model. Specifically, such transient increase in former smokers was reported for all cancer-, LC-, and COPD-related mortality. Later on, an overall decline in risk can be observed, which for LC may last over a period of 5 to 20 years. The rate of decrease in relative risk varies among the histological types of human smoking-induced LC and is slowest for adenocarcinoma. The nature of this transient increase is not fully understood, and a number of possibilities have been discussed, e.g., a bias in the response to MS inhalation seemed to weaken in this study with longer MS inhalation periods, and the responsiveness of glucocorticoid-triggered pathways might decline with age, which, taken together, could explain the long-term expression of the lung tumorigenic response in this study without the need for a postinhalation period. These findings could be interpreted as a delay of the smoke-induced tumorigenic process by concomitant smoke exposure. This interpretation is supported by the reduction in tumor size and the lower extent of malignancy in MS-exposed compared with sham-exposed mice. The lower extent of malignancy was also observed after chronic ETSS inhalation (Witschi et al., 2002). In the same way, chronic ETSS inhalation inhibited urethane-induced lung tumorigenesis in A/J mice (Stinn et al., 2005). The observations of a delayed or inhibited tumorigenesis upon concurrent smoke exposure are in line with an increased expression of senescence markers in in vitro and in vivo exposures to MS (Tsujii et al., 2004) and with smoke-induced inhibition of bronchial epithelial repair processes (Wang et al., 2001), which, when unleashed, could potentially promote tumorigenesis. Although the inhibitory effect of glucocorticoids on murine lung tumorigenesis is evident, a similar effect may also be protective in human LC development. This has been suggested by epidemiological studies in smokers undergoing glucocorticoid inhalation therapy as treatment for COPD (Kiri et al., 2009; Parimon et al., 2007).

Although the inhibitory effect of glucocorticoids on murine lung tumorigenesis is evident, a similar effect may also be protective in human LC development. This has been suggested by epidemiological studies in smokers undergoing glucocorticoid inhalation therapy as treatment for COPD (Kiri et al., 2009; Parimon et al., 2007).

A transient increase in smoking-related mortality after quitting can be observed in human former smokers (Godtfredsen et al., 2008; Knoke et al., 2008; U.S. Department of Health and Human Services, 1997), a phenomenon that was previously discussed in the context of a need for a postinhalation period to express smoking-induced tumorigenesis in the A/J mouse model. Specifically, such transient increase in former smokers was reported for all cancer-, LC-, and COPD-related mortality. Later on, an overall decline in risk can be observed, which for LC may last over a period of 5 to 20 years. The rate of decrease in relative risk varies among the histological types of human smoking-induced LC and is slowest for adenocarcinoma. The nature of this transient increase is not fully understood, and a number of possibilities have been discussed, e.g., a bias in the
population that stops smoking toward those who have been told that they are ill (the “ill quitter” effect) (U.S. Department of Health and Human Services, 1997), a latency effect in the expression of lung tumors (Knöke et al., 2008), and the sudden lack of a toxic exposure of the lung with smoking cessation (Witschi et al., 1997), which could unleash a spike in the tumorigenic development. The last two hypotheses require the persistence of at least some biological effects induced by the prior smoke inhalation in the postinhalation period. In this study, lung weights were still elevated 13 months after the end of a 5-month inhalation period, and pigmented alveolar macrophages could still be observed. Also, many inflammatory effects persisted for relatively long periods of postinhalation, and some inflammatory effects did not recover at all, most prominently in the high-concentration group. In humans, the level of smoking-related DNA adducts (Garner et al., 1990), the aberrant promoter methylation of tumor suppressor genes (Belinsky et al., 2002), and microsatellite markers of heterozygosity persist for months to years after smoking cessation (Wistuba et al., 1997), whereas other smoking-related effects reverse upon smoking cessation, e.g., pulmonary cell proliferation and squamous cell metaplasia (Lapperre et al., 2007). Smoking cessation also slows the accelerated decline of lung function in COPD patients compared with continued smoking (Godtfredsen et al., 2008). Some studies reported a recovery of inflammatory effects determined in BALF of smokers after cessation (Sköld et al., 1992), whereas other studies have shown that some inflammatory reactions to smoking, in particular regarding lymphocytic changes, may persist for years (Lapperre et al., 2006).

In contrast to human smokers, however, the current A/J mouse model did not reveal any changes in proportions of lymphocyte subpopulations upon smoke inhalation or during postinhalation periods in BALF or in bronchial lymph nodes. This does not exclude potential changes in interstitial lymphocytes, which were not specifically characterized in this study, because no MS inhalation effect on interstitial lymphocyte subpopulations was reported in a previous study (March et al., 2006). This study confirmed the general inflammatory and proteolytic effects reported by others for smoke-exposed mice, such as the neutrophil and lymphocyte influx and the change in proinflammatory cytokines, chemokines, and metalloproteinases (Braber et al., 2010; D’hulst et al., 2005; Hodge-Bell et al., 2007; March et al., 2006; Seagrave et al., 2004; Tsuji et al., 2011). However, there was no increase in the number of BALF macrophages and no preferential increase in CD8 lymphocytes as observed in some other mouse studies (Braber et al., 2010; Maeno et al., 2007; March et al., 2006), in spite of the MS inhalation–induced increase in the respective chemottractant and activating cytokines, such as MIP-1α, IFN-γ, and TNF-α. Others found a more or less parallel increase of CD4 and CD8 cells upon chronic MS inhalation as seen in this study but with an additional CD69-related activation of both types of lymphocytes (D’hulst et al., 2005). Activation markers for both airspace and interstitial lymphocytes were found to respond to MS inhalation (March et al., 2006), an effect that was not seen in this study, at least not in bronchial lymph nodes, which might provide an integrated measure of changes in the airspace and interstitial tissue. A similar pattern of reversing and persisting inflammatory effects within several weeks after termination of MS inhalation was reported in other studies confirming the sustained accumulation of lymphocytes (Braber et al., 2010; March et al., 2006; Seagrave et al., 2004) although this is the first study to extend such investigations with postinhalation periods of up to 13 months. It is unclear to what extent the method of MS generation, the MS concentration, the duration of inhalation and postinhalation periods, and the mouse strain (Morris et al., 2008; Yao et al., 2008) affect the differential pattern of inflammatory responses in these studies, but the overall inflammatory pattern observed here is generally consistent with the development of emphysematous changes in response to MS inhalation.

A further indication of stress factors, such as glucocorticoids, affecting this mouse model is the longer survival of the MS-exposed compared with the sham-exposed mice. A similar effect was observed in another chronic mouse MS inhalation study (Hutt et al., 2005), but not in others (e.g., Keast et al., 1981). In a previous rat inhalation study, prolongation of survival times was observed with the lower MS concentration but not with the higher (Mauderly et al., 2004). Thus, at MS concentrations that are high enough to considerably decrease the body weight of MS-exposed mice, i.e., to induce a certain level of stress, but not high enough to elicit overt toxicity, survival seems to be increased. This is in accordance with the general observation of increased longevity in rodents with decreased body weight as a consequence of dietary restriction (Sheldon et al., 1995). Dietary restriction also goes along with increased corticosterone levels in this mouse model (Stinn et al., 2005).

Severe dietary restriction or fasting may also lead to a degradation of pulmonary tissue with structures similar to emphysema, an effect that seems to be reversible upon refeeding (Massaro et al., 2004; Sahebjami and Domino, 1989). In this study, emphysematous changes were apparent after several months of MS inhalation and, in general, did not significantly progress or revert during the 18-month study duration, independent of whether MS inhalation was continued or stopped. When inhalation was stopped, the severe body weight decrements observed during MS exposure reverted to control levels, without parallel reversal of the emphysematous changes. The only progress that was seen for any of the morphometric endpoints was for the number of bronchial attachments, which also showed some age-dependent decrease at the last two time points, which is in line with specific aging studies (Calvi et al., 2011). Such age effects were not observed for the other two morphometric endpoints. There was also no progression of emphysematous changes in a 10-month MS inhalation study with interim evaluations using two other strains of mice (Bartalesi et al., 2005). The degree of MS-induced morphometric changes in this long-term study is similar to that observed...
in previous shorter term chronic studies with the same mouse strain (20 to 50% beyond controls), regardless of whether mice were exposed to MS (Braber et al., 2011; Foronjy et al., 2005; Guerassimov et al., 2004; March et al., 2005; Nadziejko et al., 2007) or to ETSS (Rangasamy et al., 2009).

The inflammatory reactions observed in this study may be involved in both pulmonary emphysema and tumor formation in this mouse model of MS inhalation (Bauer and Rondini, 2009; Churg et al., 2008) and in human smokers (Cosio et al., 2009; Walset et al., 2008). The risk for smoking-induced LC in patients suffering from emphysema or for emphysema in patients suffering from LC was found to be increased, even after correcting for smoke exposure (Koshiol et al., 2009; Young et al., 2009). A proteolytic imbalance (Houghton et al., 2008; Qu et al., 2009) and oxidative stress (Adcock et al., 2011) have both been suggested to be mechanistically related to this comorbidity. A laboratory animal model to further investigate the pathogenic and pathogenetic links between the two diseases has recently been called for (Punturieri et al., 2009), and the current A/J mouse model of MS inhalation–induced pathologies may serve this purpose. A further path for improved understanding of the role of inflammatory processes may be provided by a comparison of the detailed effects induced by MS versus ETSS inhalation, as after ETSS inhalation no change in the composition of inflammatory cells in BALF was found (Stim et al., 2005), although there was an increase in tumor multiplicity similar to that seen in this study.

In summary, inflammatory, emphysematous, and tumorigenic effects were observed in this MS inhalation study in a concentration- and time-dependent manner over the major part of the lifetime of the mice. This study suggests that A/J mice exposed to MS for 18 months (or combinations of shorter term chronic inhalation and postinhalation periods) provide a model for smoking-induced lung adenocarcinoma and emphysema. Tumor and emphysema data are in line with previously published shorter term chronic MS inhalation studies. This study has considerably enhanced our understanding of the changes accompanying MS exposure in mice and the potential mechanisms involved in adenocarcinoma and emphysema development. Further mechanistic research will help to substantiate the biological relevance of this model for human smoking-related diseases and to understand its limitations.

SUPPLEMENTARY DATA

Supplementary data are available online at http://toxsci.oxfordjournals.org/.

FUNDING

Philip Morris International and in part by Philip Morris USA prior to the spin-off of Philip Morris International by Altria Group on March 28, 2008. H.J.H. worked on this manuscript as a paid consultant.

ACKNOWLEDGMENTS

The authors are grateful to the technical staff at Philip Morris Research Laboratories in Leuven, Belgium, and Cologne, Germany, for their excellent work and endurance to conduct this study and to Lynda Conroy for editing the manuscript.
