ABSTRACT

We present deep Chandra X-ray observations of the core of IC 2497, the galaxy associated with Hanny’s Voorwerp and hosting a fading AGN. We find extended soft X-ray emission from hot gas around the low intrinsic luminosity (unobscured) AGN \( L_{\text{bol}} \sim 10^{42} - 10^{44} \text{ erg s}^{-1} \). The temperature structure in the hot gas suggests the presence of a bubble or cavity around the fading AGN \( E_{\text{bubble}} \sim 10^{54} - 10^{55} \text{ erg} \). A possible scenario is that this bubble is inflated by the fading AGN, which after changing accretion state is now in a kinetic mode. Other possibilities are that the bubble has been inflated by the past luminous quasar \( L_{\text{bol}} \sim 10^{46} \text{ erg s}^{-1} \), or that the temperature gradient is an indication of a shock front from a superwind driven by the AGN. We discuss the possible scenarios and the implications for the AGN–host galaxy interaction, as well as an analogy between AGN and X-ray binaries lifecycles. We conclude that the AGN could inject mechanical energy into the host galaxy at the end of its lifecycle, and thus provide a source for mechanical feedback, in a similar way as observed for X-ray binaries.

1 INTRODUCTION

IC 2497 is a massive \( (M \sim 10^{10} \text{M}_\odot) \), nearby \((z = 0.05)\) spiral galaxy associated with Hanny’s Voorwerp (HV), an extended emission line region \((11 \times 16 \text{ kpc in projected extent})\) located at \( \sim 20 \text{ kpc} \) in projection from the core of the galaxy and closely matching its redshift. HV was discovered by Hanny van Arkel,1 a citizen scientist participating in the Galaxy Zoo project (Lintott et al. 2008, 2009). The optical spectrum of HV is dominated by \([\text{O III}] \lambda \lambda 4959, 5007 \text{ Å}\) emission, and the presence of lines of high ionization species such as \([\text{Ne v}] \lambda \lambda 3346, 3426\) and \( \text{He ii} \lambda \lambda 4616 \) suggests that the cloud is photoionized by the hard continuum of an active galactic nucleus (AGN) in IC 2497 rather than star formation (Lintott et al. 2009). Moreover, the relatively quiet kinematics (line widths \(< 100 \text{ km s}^{-1}\) ) and low electron temperature \((T_e = 13500 \pm 1300 \text{ K})\) exclude the possibility of ionization from shocks (Lintott et al. 2009).

Large-scale radio observations of the system revealed an extended \( \text{H i}\) structure \((M \approx 8.5 \pm 2.1 \times 10^{10} \text{M}_\odot)\) with irregular kinematics around the southern part of IC 2497, which suggests a tidal origin (Józsa et al. 2009). These observations also show a kpc-scale structure which may be a jet coming from the AGN. HV lies where the jet meets the \( \text{H i}\) reservoir and corresponds to a local decrement of \( \text{H i}\) column density which may be due to photoionization. At smaller scales, Rampadarath et al. (2010) found a radio AGN in the core of IC 2497, and a second nuclear source which may be a jet hotspot in the large-scale jet reported by Józsa et al. (2009).

In order to produce sufficient ionizing photons to power the observed \([\text{O iii}]\) emission in HV, the quasar in IC 2497 has to have a bolometric luminosity of at least \( L_{\text{bol}} = 10^{46} \text{ erg s}^{-1} \). However, the optical nuclear spectrum shows only very weak emission lines, so that the ionizing source is classified as LINER or low-luminosity Seyfert galaxy (Lintott et al. 2009; Keel et al. 2012a). The two possible explanations to reconcile observed and expected emission

are: (1) the quasar is obscured only along our line of sight but not
in the direction of HV, or (2) IC 2497 hosts a faded AGN. This
second option would mean that the quasar dropped in luminosity
within the last ∼200 kyr, the travel time needed from the photons
to reach the cloud (Keel et al. 2012a), but HV still remains lit up
because of this travel time. Support for the fading scenario was
given by Schawinski et al. (2010) who analysed the IR data from
IRAS and X-ray data from XMM and Suzaku obtained for IC 2497.
First, as already reported inLintott et al. (2009) the IR data show no
evidence of the reprocessed luminosity expected from an obscured
strong quasar. In addition, the XMM spectrum is best fitted with an
unobscured power law with photon index $\Gamma = 2.5 \pm 0.7$, as expected
from an unobscured AGN, and a component for the hot gas in the
galaxy. The quality of the fit is not improved if additional absorp-
tion and obscuration are taken into account. This model implies a
bolometric luminosity of the AGN $L_{\text{bol}} = 4.2 \times 10^{42}$ erg s$^{-1}$, which is
∼4 orders of magnitude lower than that expected from HV. In
addition, Suzaku observations show only a marginal detection with
the 15–30 keV PIN camera (hard X-ray detector). If these counts
are real, this would mean that the AGN is strongly obscured and
we are observing the reemission instead of the AGN power law,
but the obtained luminosity would still be ∼2 orders of magnitude
below that expected from HV. Also the HST observations presented
by Keel et al. (2012a) argue against the hypothesis of a luminous,
strongly obscured AGN. WFC3 images show a complex dust struc-
ture near the nucleus of the galaxy, but the view of the nucleus is not
hindered by absorbing features, so that obscuration cannot be the
explanation of the lack of strong AGN features. Moreover, there is
no high-ionization gas near the nucleus, suggesting that the current
radiative output from the AGN is low.

The observations described above suggest that the quasar in
IC 2497 dropped in luminosity by at least 2 orders of magnitude
in the last ∼10$^5$ yr. The system composed by HV and its galaxy is
therefore a great laboratory to study AGN variability on previously
inaccessible time-scales. The analysis of the galaxy allows us to
study the present state of the AGN and the AGN-host galaxy inter-
action in this ‘post quasar’ phase, while HV provides information
about the past state of the AGN. Finally, the distance between the
two provides information about time-scales.

In this paper we present the analysis of new, deep Chandra X-ray
observations of IC 2497. The paper is organized as follows. In Sec-
tion 2 we describe the X-ray observations and the data reduction.
In Section 3 we describe the performed imaging and spectroscopic
analysis. Because of the good spatial resolution reached by Cha-
dra, this analysis allows us not only to measure the overall X-ray
flux from the galaxy, but also to (partially) resolve its emission.
In Section 4 we discuss the results and possible consequences for the
AGN–host galaxy interaction as well as the analogy between AGN
and X-ray binaries.

2 OBSERVATIONS

We observed IC 2497 with the Chandra Advanced CCD Imaging
Spectrometer (ACIS) on 2012 January 8 (ObsID 13966, 59.35 ks)
and 2012 January 11 (ObsID 14381, 53.4 ks; PI Kevin Schawin-
ski, Cycle 13). We took the data with the S-array (ACIS-S) in very
faint (VFAIN T) time-exposure (TE) mode. We performed a standard
data reduction starting from the level 1 event files using the
CIAO 4.7 software (Fruscione et al. 2006) provided by the Chandra
X-ray Center (CXC). We ran the script CHANDRA_REPRO with the lat-
est CALDB 4.6.8 set of calibration files, applied subpixel position us-
ing the Energy Dependent Subpixel Event Repositioning algorithm

(PIX_ADEF=EDSER; Tsunemi et al. 2001; Li et al. 2003, 2004), and
flagged the background events most likely associated with cosmic
rays by running the task ACIS_PROCESS_EVENTS (CHECK_VF_PHA=YES
in CHANDRA_REPRO). We analysed the background light curves with the
ciao routine lc_sigma_clip() and found no interval of unusually
strong background flaring. Because of the low count rate the
observations show no evidence of pileup.

In order to correct for the offset in the relative astrometry of the
two observations, we first rebinned the reprocessed event files to
1/4 pixel resolution (0.125 arcsec) using the CIAO DMCPY routine
with binning factor 0.75. We then ran the CIAO DMSTAT routine on the
rebinned images to get the centroid of the emission from IC 2497.
In the following we will consider the centroid as the centre of the
emission in the respective observation.

We extracted the spectra and generated the response files using
the CIAO tool SPECEXTRACT (see Section 3 for more details about the
extraction regions). For the background estimation we considered
two source-free circular regions with a 5 arcsec radius (Fig. 1, second panel).
In order to correct for any flux from the galaxy, but also to (partially)
project the ray-tracings on to the ACIS-S detector. Since we are interested in the sub-pixel regime we ran the sim-
ulations with pixadj=EDSER and AspectBlur=0.19 arcsec
telecope pointing uncertainty). We also included the telescope dithering (DitherModel=INTERNAL, DitherAmp_Ra=8,
DitherAmp_Dec=8) and corrected for SIM drift and offset.2

3 ANALYSIS

3.1 Radial profile and source extension

We compute the 0.5–6.0 keV background-subtracted surface bright-
ness profiles of the two observations starting from the reprocessed
event files. We use the CIAO tool DMSTAT to extract the counts
in four concentric annuli centred on the centroid of each exposure,
and outer radius 0.5, 1.0, 1.5 and 4.0 arcsec (Fig. 1, first panel).
For the background we consider a source-free annulus with internal
radius 4 arcsec and external radius 7 arcsec. The obtained radial
profiles, normalized to the total number of counts in a 4 arcsec
aperture, are shown in Fig. 2. The error bars correspond to the 1σ
confidence interval (68.23 per cent). For the annuli with more than
25 counts ($N > 25$) we compute the 1σ error of the total counts
(not background subtracted) using Gaussian statistic, $\sigma = \sqrt{N}$.
For $N \leq 25$ we use the Gehrels approximation $\sigma = 1 + \sqrt{N + 0.75}$
(Gehrels 1986; this actually corresponds to the 84.13 per cent upper
limit for a Poisson distribution). The profiles of the two observa-
tions are consistent within 1σ (2σ in the last annulus), showing no evidence of variability.

The emission from an AGN is expected to be point-like. However,
the radial profile suggests that the emission in IC 2497 is extended.
Moreover, the spectrum extracted from a 4 arcsec aperture is best fit
with a combination of two models: a power-law model for the AGN
emission, and a collisionally ionized diffuse gas model (APEC)

2 For details on simulating a PSF image using Marx see http://cxc.harvard.edu/chart/threads/marx_sim/
representing the hot gas in the galaxy, which can be expected to be extended (see Fig. 3 and Table 1). This is true both while performing a simultaneous fit of the two observations and considering them separately (the best-fitting parameters are always consistent within the 90 per cent confidence level; see more details about spectral fit in Section 3.2). In order to understand if the observed extension is physical, and not only due to the PSF, we compare the radial profile of the observations with the expected PSF profile. We simulate the PSF image as described in Section 2, starting from the fit to the total emission. We first create a model of the total emission using XSPEC and SHERPA, and the spectral model described above, where we also consider Galactic absorption ($\text{PHABS} \times (\text{ZPOWER} + \text{APEC})$), and then use MARX to run the ray trace simulation and project the ray-tracings onto the ACIS-S detector. In order to get a good sampling of the PSF, and thus understand its analytic shape, we increase the exposure time to $10^5$ ks. We compute the PSF brightness profile in the same way as described for the real observations. Since the PSF profile should in principle depend on the input spectrum and on the source position on the ACIS-S detector we repeat the simulations for both observations separately. However, due to the similarity of model spectra and positions (both observations are nearly on-axis) the normalized PSF brightness profiles are the same.

Fig. 2 shows the comparison between the normalized brightness profile of the source (two observations and mean value) and of the PSF. The PSF profile is steeper towards the centre than the source’s profiles. This confirms that the source is extended.

Figure 1. Left: Chandra X-ray images for Obs ID 14381 (53.4 ks), ObsID 13966 (59.35 ks), and simulated $10^5$ ks PSF. The green annuli show the regions from which we extract the spectra and compute the brightness profile. The spatial scale is the same for each image. The colour scale is linear (0–5 counts for the observations, 0–1800 counts for the $10^5$ ks PSF). Right: Chandra X-ray contours overplotted on the Hubble [O III] narrow band image of IC 2497 (top) and HV (bottom; from Keel et al. 2012a).
For both observations we use SPECEXTRACT to extract the spectrum of the total X-ray emission in IC 2497 from an aperture with \( r = 4 \) arcsec centred on the centroid. We fit the spectra in the 0.5–6.0 keV energy range with XSPEC using Cash statistic (Gehrels 1986) as fit statistic, and Chi-Square statistic as test statistic. Since there is no variability in the observations and between the observations at the 90 percent level we fit the spectra from the two data sets simultaneously. The source is best fitted as a sum of two components:

\[ \text{PL}_i \times \text{PSF}_{\text{tot}} = \text{PSF}_{\text{tot}} \]

where \( \text{PL}_i \) and \( \text{PSF}_{\text{tot}} \) are the normalization of the power-law component in the real spectra extracted from the PSF simulation. In order to fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation. In order to fit the power-law normalizations, we first fit the total emission (0.0–4.0 arcsec), and assume that for each annulus we fix the power-law slope at the value obtained from the PSF simulation.

3 Since IC 2497 is a massive galaxy, the assumption of solar abundance should be appropriate. However, we also performed the fits considering metallicities of 0.2 and 0.5 solar, and the differences in the measured temperatures are only at the \( \leq 10 \) percent level. This is true both for the total emission and for the annuli described in the next paragraphs.

4 http://xc.harvard.edu/toolkit/colden.jsp

In this way we treat the simulated spectra as similar as possible to the real spectra. We repeated the analysis also using simulated RMF and ARF files, but the fit parameters do not differ significantly.

In Fig. 4 we show the projected temperature profile (from the APEC parameter \( kT \)). We find a hint of increasing temperature from the centre towards the first and second annuli with a statistical significance above 1σ. We discuss possible implications of the found temperature gradient in Section 4. In order to understand if this...
and measure the temperature in the same annuli as used for the analysis. Each bin corresponds to one annulus defined in Fig. 1. The purple points correspond to the real data. There is a hint of a temperature gradient, which could indicate the presence of a bubble powered by the central AGN. The grey shaded area corresponds to the temperature profile measured in the hot gas which is kinematically inflated by the AGN. Alterna-
tively, the temperature gradient could indicate a shock front, e.g. in the hot gas that is due to the PSF effect. We simulate a PSF (see Section 3.2 for more details). This temperature gradient may be interpreted as a bubble or cavity, which could indicate the presence of a bubble powered by the central AGN. We associate this emission with a hot, diffuse gas. The pro-
cedure. We repeat the fit of the real data without fixing the gradient as that reported by Schawinski et al. (2010). As reported by Schawinski et al. (2010), if the AGN is Compton thick, this would mean that it is strongly obscured and we are observing the intrinsic gas parameters.

Table 1. Best-fitting parameters for each region considered in this analysis (nucleus, three annuli, four semi-annuli). The assumed model is PHABS × (ZPOW + APEC). In the nucleus, all the fit parameters are free. The power-law slope and normalization are fixed according to the PSF simulation (see text for details). Abundance is fixed at solar value and absorption at Galactic value (N_H = 1.31 × 10^{20} cm^{-2}).

| Region                  | Net counts | PL slope       | PL norm (10^{-7}) | Temperature (keV) | APEC norm (10^{-7}) |
|-------------------------|------------|----------------|-------------------|-------------------|---------------------|
| Total emission (0.0–4.0 arcsec) | 620        | 2.33^{+0.18}_{-0.16} | 67.486^{+9.453}_{-9.162} | 0.953^{+0.048}_{-0.054} | 38.735^{+16.558}_{-6.381} |
| Nucleus (0.0–0.5 arcsec)   | 262        | 2.47           | 46.708            | 0.702^{+0.211}_{-0.212} | 5.193^{+1.941}_{-1.823} |
| Annulus 1 (0.5–1.0 arcsec) | 221        | 2.31           | 15.387            | 1.133^{+0.100}_{-0.111} | 21.143^{+4.293}_{-3.974} |
| Annulus 2 (1.0–1.5 arcsec) | 52         | 1.89           | 2.019             | 1.003^{+0.248}_{-0.120} | 5.023^{+1.077}_{-1.130} |
| Annulus 3 (1.5–4.0 arcsec) | 84         | 1.65           | 1.213             | 0.809^{+0.158}_{-0.080} | 10.013^{+1.425}_{-1.315} |
| Semi-ann. 1 (45–135°)     | 54         | 2.28           | 3.709             | 1.064^{+0.249}_{-0.123} | 5.185^{+2.893}_{-1.277} |
| Semi-ann. 2 (135–225°)    | 56         | 2.37           | 3.881             | 0.920^{+0.105}_{-0.139} | 5.316^{+3.343}_{-1.180} |
| Semi-ann. 3 (225–315°)    | 55         | 2.27           | 3.709             | 1.575^{+0.343}_{-0.343} | 7.933^{+7.583}_{-3.163} |
| Semi-ann. 4 (315–405°)    | 55         | 2.29           | 3.886             | 1.283^{+0.386}_{-0.185} | 7.401^{+4.406}_{-2.173} |

The temperature increase showed in Fig. 4 could be symmetric, or due to a feature in a preferred direction. In order to investigate these possibilities we repeat the analysis dividing the first annulus (0.5–1.0 arcsec) into four semi-annuli of 90° each. The results are listed in Table 1. Because of the lower number of counts in each region, these fits are less reliable than the one to the total annulus. However, the temperature gradient seems to be present in each direction, although it is more important in the southern part. This seems to rule out the possibility of a single feature with significantly higher temperature.

It is important to note though that the low number of counts in our spectra do not allow us to deproject the emission from the different shells, so that the reported gas temperatures and normalizations are projected values along the line of sight. A deeper ∼1 Ms Chandra exposure will allow us to obtain a minimum of 200 counts in all region of interest, and thus properly deproject the emission and carefully measure the intrinsic gas parameters.

4 DISCUSSION

We detect extended soft X-ray emission in the nucleus of IC 2497, in addition to the point-like power-law emission expected from an AGN. We associate this emission with a hot, diffuse gas. The projected temperature profile (Fig. 4) shows a resolved cold centre. The temperature gradient may be interpreted as a bubble or cavity in the hot gas which is kinematically inflated by the AGN. Alternatively, the temperature gradient could indicate a shock front, e.g. from an AGN-driven superwind. The different hypothesis, and the consequences for the AGN-host galaxy interaction, is described in the following subsections.

The current analysis also supports the idea that IC 2497 hosts a fading AGN, as suggested by Lintott et al. (2009), Schawinski et al. (2010) and Keel et al. (2012a). In fact, by scaling the quasar spectral energy distribution (SED) templates from Elvis et al. (1994) to match the measured X-ray luminosity, L_{2–10 keV} ≈ 5.8 × 10^{40} erg s^{-1}, we obtain a bolometric luminosity L_{bol} ≈ 10^{42} erg s^{-1}, which is ∼4 orders of magnitude below what is needed in order to power HV (Lintott et al. 2009; Schawinski et al. 2010). This result is consistent with that reported by Schawinski et al. (2010). As reported by Schawinski et al. (2010), if the AGN is Compton thick, this would mean that it is strongly obscured and we are observing the
reemission instead of the AGN power law, and the bolometric luminosity would be \( L_{\text{bol}} \approx 10^{44} \text{ erg s}^{-1} \) (see Section 1). This is still \( \sim 2 \) orders of magnitude below what is needed in order to power HV. Hard X-ray observation from \( \text{NuSTAR} \) is now crucial in order to understand if the AGN is obscured and measure the real magnitude of the shutdown.

4.1 Hot gas in IC 2497

The projected temperature observed in the gas in IC 2497 is in the range \( kT \approx 0.7–1.1 \text{ keV} \) \((T \approx 0.8–1.2 \times 10^{7} \text{ K})\). This relatively high temperature may indicate that the emission from the hot gas is not due to photoionization, as seen in other Seyfert galaxies (e.g. Bianchi, Guainazzi & Chiaberge 2006; Greene et al. 2014). On the other hand, the projected temperature measured in the centre and in the external annulus is consistent with that found in ULIRGs (Grimes et al. 2005). The high projected temperature, especially in the two central annuli, may be an indication that we are observing a shock front, e.g. from AGN-driven superwinds. Models of AGN-driven superwinds suggest a temperature of \( T \approx 10^{10–10^{11}} \text{ K} \) for the inner reverse shock and \( T \approx 10^{7} \text{ K} \) for the forward shock, and the expanding medium can persist also after the AGN has switched off (Zubovas & King 2012). The observed temperatures are consistent with the forward shock, but too low for the inner shock. Is the AGN in IC 2497 too faint to produce such a high temperature? Or is the observed shock front a residual of a wind driven by the AGN during the past quasar phase? Deeper X-ray observations (leading to X-ray spectra with more counts) will allow us to deproject the emission and carefully constrain the intrinsic temperature, density and X-ray luminosity of the gas in each shell around the AGN. This will allow us to estimate the velocity of the shock and the ratio between X-ray and mechanical luminosity (e.g. Chu & Mac Low 1990), and therefore probe the superwind hypothesis and constrain between the two scenarios.

Another possible interpretation of the observed projected temperature gradient is that the AGN is, or was, blowing away the hot gas around it by injecting kinetic energy, therefore creating a bubble or cavity. If the hypothesis of a bubble inflated by a fading AGN is confirmed, this would give us new insights into the AGN–host galaxy interaction in the ‘post-quasar’ phase, as described below. It is important to note that though the low number of counts in our spectra does not allow us to deproject the emission from the different shells, so that the reported gas temperatures and normalizations are projected values along the line of sight. A deeper \( \sim 1 \text{ Ms} \) \( \text{Chandra} \) exposure will allow us to obtain a minimum of 200 counts in all region of interest, and thus properly deproject the emission and carefully measure the gas parameters. In this way we will be able to further test the bubble hypothesis.

4.2 Energy in the bubble

In order to understand the effect of the AGN on the surrounding medium we need to estimate the energy in the bubble, i.e. the energy required to create it. The uncertainties in this calculation are quite high due to the uncertainties in the spectral fitting and the unknown shape of the bubble and hot gas. Therefore, the obtained energy should be seen as an order of magnitude estimation. One possible way to approach the problem is to consider an analogy with the cavities observed in clusters (e.g. Birzan et al. 2004; Rafferty et al. 2006; McNamara & Nulsen 2012; Vantyghem et al. 2014). In this case the energy needed to create the bubble can be expressed as:

\[
E_{\text{bub}} = \frac{\gamma}{\gamma - 1} p V_{\text{bub}}
\]

(2)

where \( p \) is the pressure of the gas surrounding the bubble, \( V_{\text{bub}} \) is the bubble’s volume, and \( \gamma \) is the heat capacity ratio of the gas inside the bubble \((\gamma = 4/3 \text{ for a relativistic gas, } \gamma = 5/3 \text{ for a non-relativistic, monoatomic gas})\). For our estimation we consider a spherical bubble with radius \( r = 1 \text{ arcsec} \), corresponding to \( r = 987 \text{ pc} \) at the redshift of the source. The pressure \( p \) can be expressed as:

\[
p = n(kT),
\]

(3)

where \( n \) and \( kT \) are the number density and temperature of the gas outside the bubble, as derived from the spectral fit to the third annulus \((1.5–4.0 \text{ arcsec})\). For a fully ionized gas with 10 per cent He we can assume \( n_e \sim n_{H} \) and \( n \sim 2n_e \), so that \( n \) can be derived from the \( \text{APEC} \) normalization:

\[
\text{NORM} = \frac{10^{-14}}{4\pi D^2_h (1 + z)^2} \int n_e n_H \text{ dV},
\]

(4)

where we consider the normalization obtained in the third annulus, while the volume corresponds to a napkin ring for a sphere with \( r = 4 \text{ arcsec} \) and a cylinder with \( r = 1.5 \text{ arcsec} \) (i.e. the volume of the external shell which is projected into the third annulus). In this way we obtain \( n \approx 0.02 \text{ cm}^{-3} \) and \( p \approx 2.5 \times 10^{-11} \text{ erg cm}^{-3} \), so that the energy in the bubble is \( E_{\text{bub}} \approx 10^{52–53} \text{ erg} \).

Now we will carry out comparisons to test what these numbers can tell us about the bubble itself and the effect of the AGN on the host galaxy. The energy in the bubble is \( \sim 3–4 \) orders of magnitude higher than that expected from a supernova explosion, so that the bubble cannot be inflated by supernovae. Keel et al. (2012a) found a ring of ionized gas on the northern part of the nucleus of IC 2497. The ring has a radius \( r \approx 250 \text{ pc} \) which can be seen in both \( \text{HST} \) \( \text{H} \alpha \) and \( \text{[O III]} \) continuum images, and with a kinematic age \( <7 \times 10^6 \text{ yr} \) (see fig. 5 in Keel et al. 2012a). The kinetic energy in this ring is \( \sim 3 \times 10^{51} \text{ erg} \), \( \sim 3–4 \) orders of magnitude lower than that found in our bubble, and also the spatial extent is different. This is an indication that additional components need to be considered, probably happening at the same time, near the nucleus of IC 2497. Finally, the binding energy of IC 2497 is \( \sim 10^{60} \text{ erg} \), which means that the present-day AGN is not able to blow away the whole ISM. However, Schawinski et al. (2015) recently suggested that AGN ‘flicker’ on and off 100–1000 times alternating high-Eddington bursts and lower-Eddington troughs points, with a typical AGN phase lasting \( \sim 10^7 \) yr. If what we observe in IC 2497 is typical to each burst, i.e. the AGN injects \( \sim 10^{59} \) erg in each cycle, the sum of the energy injected in each cycle could start having some effect on the gas reservoir (although alone it would probably be insufficient to totally unbind it). Finally, if we assume that the bubble is inflated by the fading AGN after the quasar drop in luminosity (i.e. in the last \( \sim 2 \times 10^7 \) yr), the AGN should inject at least \( \sim 10^{42} \text{ erg} \) in kinetic form, and the bubble should expand with a velocity \( v_{\text{exp}} \sim 5000 \text{ km s}^{-1} \).

4.3 Accretion state changes, AGN feedback and analogy with X-ray binaries

As explained above, one possible interpretation of the bubble is that it is inflated by the fading AGN after the quasar drops in luminosity, and we are witnessing a state change in the accretion mode of the quasar. After dropping in accretion rate, the low-Eddington AGN moved from a radiative mode to a kinetic mode, and now puts out...
part of its energy in kinetic form. In this way, it can do a feedback on the galaxy, e.g. by inflating a bubble in the surrounding gas or launching the radio jets. The hypothesis of a state change in IC 2497 is consistent with the analysis done by Keel et al. (2012a). In fact, the HST STIS spectra and images indicate the presence of an outflow from the nucleus which suggests that some of the energy output from the AGN switched from radiation to kinetic form.

The idea of a bubble inflated by an AGN undergoing a state change fits naturally into the general picture of unifying black hole (BH) accretion physics from X-ray binaries (XRB) to AGN. Rapid state transitions, on time-scales of days to weeks, are often observed in XRB, and are connected to a change in radiative output (e.g. Fender, Gallo & Jonker 2003; Coriat et al. 2011; Eckersall, Vaughan & Wynn 2015). The luminous soft state is radiatively efficient and the accretion can be described by an optically thick, geometrically thin accretion disc (Shakura & Sunyaev 1973). On the other hand, the hard state is radiatively inefficient and the accretion is due to an advection-dominated (ADAF; Narayan & Yi 1995) or jet-dominated accretion flow (JDAF; Falcke, Körding & Markoff 2004), so that most of the energy output from the accreting BH is in kinetic form. The hypothesis of a state switch connected to the drop in luminosity is consistent also with Done, Gierliński & Kubota (2007) which show that, as the Eddington ratio decreases, the radiative power of an XRB decreases while the mechanical/kinetic power increases. Alexander & Hickox (2012) suggested that this is true also for AGN. In this framework, low-luminosity AGN correspond to the hard XRB, while the quasars correspond to the soft state. Different studies showed that the AGN accretion discs can indeed change their state from a classical radiatively efficient quasar state to a radiatively inefficient accretion flow in a similar way as observed in X-ray binaries. However, since the dynamical and viscous time-scales involved in the accretion state changes increase with BH mass, the time-scales expected for AGN are significantly longer (e.g. Narayan & Yi 1995; Maccarone, Gallo & Fender 2003; Körding, Jester & Fender 2006; McHardy et al. 2006; Schawinski et al. 2010). As an example, the analogous of a state transition lasting several days in an X-ray binary with an ∼10M⊙BH will last ∼10^3 yr in an AGN with an ∼10^4 M⊙ supermassive black hole. These time-scales are consistent with that seen in IC 2497.

5 SUMMARY

We have presented new, deep Chandra X-ray observations of IC 2497. This galaxy is associated with the extended emission line cloud called Hanny’s Voorwerp and hosts a fading AGN. The X-ray data show extended hot gas around the very low luminosity unobscured AGN (L_2–10 keV ∼10^40 erg s^-1). Moreover, the data suggest a temperature gradient in the hot gas which may be interpreted as an expanding bubble (r_{hub} ∼ 1 kpc, v_{hub} ∼ 10^5–10^5 cm s^{-1}). One hypothesis is that this bubble is inflated by the AGN that, after changing accretion state and dropping in luminosity, is now in a kinetic mode. As a consequence, the right place to search for and study mechanical AGN feedback could be galaxies hosting fading AGN (i.e. the Voorwerpjes, Keel et al. 2012b, 2015). The idea of an AGN doing mechanical work at the end of its radiatively efficient phase also fits into the general picture of unifying BH accretion physics from X-ray binaries to AGN. Follow-up deeper Chandra observations will allow us to confirm the presence of the bubble and better constrain its properties and its effect on the host galaxy.

ACKNOWLEDGEMENTS

LFS, KS and MK gratefully acknowledge support from Swiss National Science Foundation Professorship grant PP00P2_138979/1 and MK support from SNSF Ambizione grant PZ00P2_154799/1. LS thanks Claudio Ricci and Hans Moritz Günther for useful discussions. OIW acknowledges a Super Science Fellowship from the Australian Research Council.

This work is based on observations with the Chandra satellite and has made use of software provided by the Chandra X-ray Center (CXC) in the application packages CIAO and MARX. The research has made use of NASA’s Astrophysics Data System Bibliographic Service.

Extended X-ray emission in IC 2497

3635

MNRAS 457, 3629–3636 (2016)
APPENDIX A: X-RAY SPECTRA AND XSPEC FITS

Figure A1. Chandra X-ray spectra extracted from the nuclear region and from the three annuli, for ObsID 14381 (black) and ObsID 13966 (grey). The spectra are binned so that each bin contains at least three counts. The lines correspond to the best-fitting model PHABS × (ZPOW + APEC), where ZPOW corresponds to the AGN emission and APEC to the emission from a hot diffuse gas (see text). The absorption is fixed to the Galactic value. The residuals of the fit are shown in the bottom panel.
