Network Coding Based Evolutionary Network Formation for Dynamic Wireless Networks

Minhae Kwon, Student Member, IEEE and Hyunggon Park, Senior Member, IEEE

Abstract—In this paper, we aim to find a robust network formation strategy that can adaptively evolve the network topology against network dynamics in a distributed manner. We consider a network coding deployed wireless ad hoc network where source nodes are connected to terminal nodes with the help of intermediate nodes. We show that mixing operations in network coding can induce packet anonymity that allows the inter-connections in a network to be decoupled. This enables each intermediate node to consider complex network inter-connections as a node-environment interaction such that the Markov decision process (MDP) can be employed at each intermediate node. The optimal policy that can be obtained by solving the MDP provides each node with optimal amount of changes in transmission range given network dynamics (e.g., the number of nodes in the range and channel condition). Hence, the network can be adaptively and optimally evolved by responding to the network dynamics. The proposed strategy is used to maximize long-term utility, which is achieved by considering both current network conditions and future network dynamics. We define the utility of an action to include network throughput gain and the cost of transmission power. We show that the resulting network of the proposed strategy eventually converges to stationary networks, which maintain the states of the nodes. Moreover, we propose to determine initial transmission ranges and initial network topology that can expedite the convergence of the proposed algorithm. Our simulation results confirm that the proposed strategy builds a network which adaptively changes its topology in the presence of network dynamics. Moreover, the proposed strategy outperforms existing strategies in terms of system goodput and successful connectivity ratio.

1 INTRODUCTION

The connected world which began with representative services such as connected cars, networked unmanned aerial vehicles (UAVs), multi-robot systems, and the Internet of things (IoT), results in networks with inherent dynamics. The network entities of such services generally have high mobility, which causes frequent changes in member nodes associated with these networks. Moreover, the links between the network entities may be under unstable channel conditions with high link failure rates. Hence, it is essential to form robust networks against such dynamics by adaptively reformulating inter-connections among network entities. However, solving this problem based on conventional centralized solutions requires very high computational complexity such that it cannot be practically considered. Rather, it can be solved by decentralized and spontaneous network formation strategies that enable each network entity to make proactive and adaptive decisions on network topology against the network dynamics. In wireless ad hoc networks, for example, source nodes are connected to terminal nodes via mobile intermedia nodes. Then, the network topology can be determined in a distributed manner based on decisions of mobile intermediate nodes for transmission ranges. In order to overcome network dynamics, each mobile intermediate node may strategically change its transmission range. Such distributed strategies for network formation can be essential in circumstances where only limited infrastructures can be available, e.g., disaster networks or military networks.

However, it is not straightforward to design decentralized strategies that enable each network entity to make its own and optimal decisions, because the network entities are intimately coupled. Specifically, the network entities can be tightly inter-connected, so that the impact of small changes from a network entity may propagate over a large number of entities. Thus, each network entity should consider the corresponding responses associated with its decisions to make optimal decisions. This may require significantly high computational complexity or may not be feasible in practice. Therefore, it is essential for the design of decentralized strategies to decouple the inter-connections among network entities.
entities.

In this paper, we show that the inter-connections among network entities can be decoupled by deploying network coding, which is referred to as network decoupling. Unlike the conventional store-and-forward approach, network coding [1] allows an intermediate entity to combine multiple packets that it has received and to forward the mixed packets. For a network coding enabled wireless ad-hoc network (which is widely considered as a network model of a connected world), a packet passes through many intermediate entities. Thus, it can be mixed with other packets multiple times. This leads to packet anonymity, where all packets in the network eventually have identical information including their terminal nodes. Packet anonymity allows an entity to consider the other entities as its environment. Hence, complicated inter-connections among network entities can be decoupled, and only the connection directly associated with the entity is considered as a one-hop connection. This leads to network decoupling so that the interactions between network entities can be interpreted as a node-environment interaction at each entity. An illustrative example of wireless ad hoc network with network coding is shown in Fig. 1.

In this example, source nodes are connected to terminal nodes via mobile intermedia nodes with network coding functionality.

Motivated by the node-environment interaction, we use an MDP to find a decentralized strategy which is referred to as a policy for network formation. We consider wireless entities to be autonomous decision-making agents and the state of an agent is defined as the number of effective nodes. Here, effective nodes are the entities that have successfully received packets from the agent. The probability density function of the states is modeled by the Poisson point process (PPP), which is widely used to characterize the behavior of mobile nodes. The action of an agent is defined as the amount of increasing or decreasing transmission range, which is the outcome of the policy for the current state of the agent. The policy is optimal if it enables the agent to maximize long-term utility.

As a node increases its transmission range, the number of hops required to reach the terminal node decreases, without loss of generality, leading to an improvement in network throughput. However, extending the transmission range increases transmission power consumption and causes more inter-node interference. This is explicitly captured by the utility function, which represents both network throughput improvement and the additional transmission power. Therefore, the optimal policy enables each entity to successively determine the optimal changes in transmission range at each state, such that the entities can strike a balance between network throughput gain and power consumption. Finally, the consequences of the distributed decisions from each entity eventually determine the network topology.

Note that the proposed strategy allows the resulting network topology to evolutionarily adapt against network dynamics. This is because the state is defined by the effective nodes, which are directly dependent on link failure rates (i.e., channel condition) and node mobility (i.e., node distribution). For example, a larger transmission range may be required in a channel with higher link failure rates for the target number of effective nodes. Similarly, an agent can increase its transmission range to sustain connectivity in the case of sparse node density. The proposed strategy is also robust against frequent changes in member nodes of the considered network, which is widely observed in mobile networks. This is because the behavior of existing nodes is not affected by individual network members, instead it is only affected by the number of effective nodes included in its own transmission range.

Unlike conventional optimal solutions that focus on maximizing immediate utility, the proposed optimal policy determined by the MDP can provide a long-term strategy, which determines actions by explicitly considering future dynamics in the network. Specifically, the actions taken by the optimal policy can maximize the long-term utilities, which are expressed as the sum of discounted utilities over time. The discount factor can be determined by considering the consistency of network conditions. Therefore, the actions determined by the proposed policy can consider both current and future network dynamics.

The proposed system consists of two phases: initialization and adaptation. In the initialization phase, the optimal policy for each intermediate node is found and the state can be initialized. As will be shown in this paper, optimal actions can lead the network formation result to certain topologies, referred to as stationary networks. Hence, we design the initial network to be close to the stationary network. In the adaptation phase, each node adaptively and optimally changes its transmission range based on the optimal policy for the current state induced by network dynamics.

The main contributions of this paper are summarized as follows.

- We show that network coding can lead to packet anonymity where both the information and terminal of all packets in network asymptotically become identical, and
- We show that the packet anonymity of network coding allows inter-connections among network nodes to be decoupled into node-environment interactions at each node, which is referred to as network decoupling,
- We formulate the problem of network topology formation in an MDP framework and provide a decentralized solution to the network formation strategy,
- The proposed strategy improves network robustness by adaptively rebuilding its topology in the presence of network dynamics which includes unstable channel conditions with high link failure rates, and high mobility of network nodes that causes frequent changes in member nodes associated with the considered network,
- The proposed strategy is a foresighted strategy that chooses the action maximizes a long-term utility by considering future network dynamics,
- The proposed strategy can determine the optimal transmission range that balances network throughput improvement and transmission power consumption,
- The resulting network of the proposed strategy converges to stationary networks, and
- We propose how to initialize a network such that the speed of convergence to the stationary network can be improved.

Note that the focus of this paper is neither on the code design for network coding which has been extensively studied in prior works [2], [3], [4], [5], [6], [7], [8], [9], nor on
perfect delivery which needs 100% reliability. Rather, our focus is on robust network formation based on network coding, which can proactively reform network topology against network dynamics in a decentralized manner.

The rest of the paper is organized as follows. In Section 2, we briefly review related works. The wireless model for mobile users and detailed process of data delivery based on network coding are discussed in Section 3. The MDP-based framework and a distributed network formation strategy are proposed in Section 4 and Section 5, respectively. Simulation results are presented in Section 6, and conclusions are drawn in Section 7.

For the reader’s convenience, we summarize notations frequently used in this paper in Table 1.

## 2 Related Works

Since network coding was first introduced in [1], it has shown excellent ability to improve throughput, robustness and complexity. The beginning of network coding was for throughput gain in a multicast scenario. In [2], it is shown that network coding can achieve maximum throughput via the max-flow min-cut theorem, and it is further proved that linear network coding can achieve the upper bound of capacity in [3]. Many works in network coding have been studied for random linear network coding (RLNC) [4] as it is a simple, randomized encoding approach that is decentralized [5], [6]. As well as throughput gain, it has been shown that network coding also enhances robustness against packet loss in lossy wireless networks [7], [8], [9].

Another advantage of network coding is that there is a lower complexity requirement for network formation compared to a conventional store-and-forward approach. In a conventional store-and-forward approach, it is difficult to find the optimal routing path that can achieve the capacity upper bound. Even though an optimal routing solution exists in some cases, such as the Steiner tree in multicast routing, finding the solution is still very complex within a centralized setting [10]. Network coding, however, can transform complex network formation problems into low-complexity distributed problems. For example, a distributed solution that satisfies optimality condition to minimum delay and minimum energy consumption is proposed in [11]. Decentralized algorithms for network formation that can minimize cost per unit capacity are proposed in [12].

Even though network coding can reduce complexity in general, it is known that finding an optimal solution in network coding with multiple multicaist is an NP-hard problem [13]. Hence, suboptimal but practical solutions are often studied [14], [15]. A well-known practical solution to network formation is proposed based on linear optimization in [16]. In [17], a distributed network formation solution is developed for network coding deployed wireless networks that includes multi-source multicast flows. Using a game theoretical approach, each node in the network determines its transmission power and the use of network coding operations.

Network formation strategies for dynamic network conditions in conventional routing schemes have been widely studied in the context of a self-organizing network. Protocols for self-organization of wireless sensor networks where there exists a large number of static nodes with energy constraints are described in [18]. In [19], an emergency communication system based on UAV-assisted self-organizing network is considered. In this work, UAVs are used as a strong relay node to form a relay network in the air, and the nodes on the ground formed a self-organizing network automatically with the help of UAVs. In [20], a dynamic topology control that prolongs the lifetime of a wireless sensor network is proposed based on a non-cooperative game.

However, there have been few studies in network coding deployed network formation strategies that are robust in the presence of network dynamics.

## 3 Network Coding Deployed Wireless Ad Hoc Networks

### 3.1 Wireless Ad Hoc Network Model

We consider a wireless ad hoc network modeled by a directed graph $G_r$, comprising a set $V(G_r)$ of nodes together with a set $E(G_r)$ of directed links at time $\tau$. Let $v_i \in V(G_r)$ be the $i$-th element in $V(G_r)$, and there are three types of nodes in the network: source, intermediate and terminal. Let $\mathbf{h}$ be an index set of source nodes and its element is denoted as $h \in \mathbf{H}$. An index set of terminals for a source node $v_h$ is denoted as $\mathbf{T}_h$, and the data that $v_h$ generates at time $\tau$ are denoted as $x_{h,\tau}$. In this paper, we consider the multi-source multicast flows that have multiple source nodes, and each source node has an independent set of terminal nodes. Specifically, a source node $v_h$ for $h \in \mathbf{H}$ aims to deliver its data $x_{h,\tau}$ to multiple terminal nodes $v_{h,\tau} \in \mathbf{T}_h$ so that $\sum_{h \in \mathbf{H}} |\mathbf{T}_h|$ flows are simultaneously considered, where $|\cdot|$ denotes the size of a set. The total index set of all terminals in $G_r$ is denoted as $\mathbf{T} = \bigcup_{h \in \mathbf{H}} \mathbf{T}_h$, and the number of source nodes and terminal nodes are denoted by $N_H$ and $N_T$, respectively. The source nodes can only transmit data but cannot receive data, and the terminal nodes can only receive data but cannot transmit data, unlike the source nodes.

In cases where the source nodes are not able to directly transmit data to the terminal nodes, intermediate nodes can relay the data by receiving and transmitting the data. Let $v_i$ for $i \in \mathbf{V}$ be an intermediate node where $\mathbf{V}$ denotes an index set of intermediate nodes, and $N_V$ be the number of intermediate nodes. Then, the total number of nodes in the network can be represented by $|V(G_r)| = N_H + N_V + N_T$.

We consider the intermediate nodes as wireless mobile devices that can move around in a bounded region with energy constraints. We use a stochastic geometry model to capture the distribution of intermediate nodes to model the characteristics of mobility; the number of intermediate nodes in a bounded region follows an independent homogeneous PPP with node density $\lambda$, which is the expected number of Poisson points [21], [22]. Moreover, each intermediate node can adjust its transmission power, which determines the range of potential delivery of data from the node, which is referred to as transmission range. Let $\delta_i,\tau$ and $\delta_{i,\tau}(v_j)$ be the radius of the transmission range of $v_i$ and the Euclidean distance from node $v_i$ to node $v_j$ at time $\tau$, respectively. Then, $v_j$ is located in the transmission range of $v_i$ if $\delta_{i,\tau}(v_j) < \delta_i,\tau$.
TABLE 1: Summary of Notations

| Notation | Description | Notation | Description |
|----------|-------------|----------|-------------|
| $v_i$    | a node with index $i$ | $S$     | state space |
| $H_i$    | an index set of source nodes for a terminal node $v_i$ | $s$     | a state |
| $H$      | an index set of source nodes | $A$     | action space |
| $T_h$    | an index set of terminals for a source node $v_i$, for $h \in H$ | $a$     | an action |
| $T$      | total index set of all terminals in $G_s$ | $\bar{a}_s$ | transmission range at time $\tau$ |
| $V$      | an index set of intermediate nodes | $\rho$ | discount factor |
| $\lambda$ | node density in network | $\omega$ | weight in (12) |
| $\Gamma_i,\tau(v_j, T_h)$ | node value function | $R(s, s')$ | reward |
| $\delta_i,\tau(v_j)$ | the Euclidean distance from node $v_i$ to node $v_j$ at time $\tau$ | $\pi$ | policy |
| $\delta_i,\tau$ | the radius of intermediate node $v_i$’s transmission range at time $\tau$ | $V_p(s)$ | state-value function |
| $\Delta_\tau(v_j, v_t)$ | the number of hops between $v_j$ and $v_t$ at time $\tau$ | $\sigma$ | limiting distribution |
| $\Delta_\tau(v_j, T_h)$ | a set of $\Delta_\tau(v_j, v_t)$ for all $t \in T_h$ | $\sigma_s$ | limiting probability of state $s$ |
| $P$      | network coding function | $P$     | state transition matrix |

$v_i$ if $\delta_i,\tau(v_j) \leq \bar{\delta}_i,\tau$ and $v_j$ can receive the data from $v_i$. We assume that links between nodes may be disconnected with probability $\beta$, which is referred to as the link failure rate. Hence, the probability that $v_j$ in the transmission range of $v_i$ can successfully receive the data from $v_i$ is given by $1 - \beta$.

The deployment of intermediate nodes naturally leads to a multi-hop ad hoc network, and thus, the network throughput highly depends on the selection of paths constructed by the nodes. Therefore, node $v_i$ needs to choose a node $v_j$, which can relay the data to terminal nodes $T_h$ better than other neighbor nodes in terms of node values. The node value of $v_j$ from the perspective of $v_i$ is evaluated by the node value function $\Gamma_i,\tau(v_j, T_h)$, expressed as

$$\Gamma_i,\tau(v_j, T_h) = f(\delta_i,\tau(v_j), \Delta_\tau(v_j, T_h))$$  \hspace{1cm} (1)

where $\Delta_\tau(v_j, T_h) = \{\Delta_\tau(v_j, v_t) | v_t \in T_h\}$ and $\Delta_\tau(v_j, v_t)$ denotes the number of hops between $v_j$ and $v_t$ at time $\tau$. The function $f(\delta_i,\tau(v_j), \Delta_\tau(v_j, T_h)) : (\bar{R}, \mathbb{W}^{\{T_h\}} \times \bar{R}) \rightarrow \bar{R}$ is a decreasing function of $\delta_i,\tau(v_j)$ and $\Delta_\tau(v_j, T_h)$, where $\bar{R}$ denotes the field of real numbers and $\mathbb{W} = \{0, \mathbb{Z}^+\}$ denotes the whole numbers which includes zero and the positive integers $\mathbb{Z}^+$. By defining the node value as a decreasing function of the distance and the number of hops from $v_j$ to $v_t$, $\Gamma_i,\tau(v_j, T_h)$ increases as $v_j$ is located closer to $v_t$, and $v_j$ is connected to $v_t$, $\forall t \in T_h$, with a smaller number of hops. Therefore, $v_i$ consumes lower transmission power with a smaller transmission range and reduces delay for data delivery for appropriate selection of $v_j$.

### 3.2 Network Coding Based Encoding Process

A source node $v_h$ for $h \in H$ generates a set of data $x_{h,\tau} = \{x_{h,\tau,1}, \ldots, x_{h,\tau,L_h}\}$ at time $\tau$ and it broadcasts $x_{h,\tau}$ with the transmission power $a_h = g(\delta_h)$, where the function $g : \bar{R} \rightarrow \bar{R}$ is determined based on a path loss model of wireless channels. We assume that the radius of transmission range $\delta_h$ of $v_h$ is stationary (i.e., time independent), so that the subscription $\tau$ is omitted. If an intermediate node $v_i$ is located in the transmission range of $v_h$ at time $\tau$, $v_i$ receives $x_{h,\tau}$, and puts $x_{h,\tau}$ into its buffer $L_i$, i.e., $x_{h,\tau} \in L_i$, wherein data are sorted by time stamp $\tau$ with the oldest time stamp at the head of the queue [28]. Note that the packet has a limited life span (e.g., time to live (TTL) in an internet packet) such that the packets with an expired time stamp can be discarded. For simplicity, we assume that the output capacity of a node is a single packet size such that a node transmits a single packet per unit time [29], [30], [31], and a node can receive multiple individual packets by applying multipacket reception techniques [32], [33].

The intermediate node $v_i$ performs network coding operations by combining packets with the same time stamp in $L_i$ and generates encoded data $y_{i,\tau+1}$ at time $\tau+1$ expressed as

$$y_{i,\tau+1} = \sum_{h=1}^{N_H} \bigoplus (C_{hi,\tau+1} \otimes x_{h,\tau})$$  \hspace{1cm} (2)

where $C_{hi,\tau+1}$ denotes the global coding coefficient of $v_i$ for source data $x_{h,\tau}$. The network coding operations are performed in the Galois field (GF) and the operators $\oplus$ and $\otimes$ denote the addition and multiplication in GF, respectively. When the encoding process is performed in [2], the source data with the same time stamp are combined together, and a packet $p_{i,\tau+1}$ is constructed as

$$p_{i,\tau+1} = [\tau, C_{i1,\tau+1}, \ldots, C_{Ni,\tau+1}, y_{i,\tau+1}]$$

which has the time stamp of the combined source data $\tau$, the global coding coefficient $C_{hi,\tau+1}, \forall h \in H$ as the header, and the encoded data $y_{i,\tau+1}$ as a payload. An index set of terminals for $p_{i,\tau+1}$ denoted by $T_{p_{i,\tau+1}}$ can be expressed as

$$T_{p_{i,\tau+1}} = \bigcup_{h \in \{h|C_{hi,\tau+1} \neq 0, \forall h \in H\}} T_h.$$  \hspace{1cm} (3)

This is because $p_{i,\tau+1}$ needs to be delivered to all terminals of combined source data, i.e., for all $v_t \in T_h$ and $h \in \{h|C_{hi,\tau+1} \neq 0, \forall h \in H\}$.

If the intermediate node $v_i$ receives the encoded packets $y_{i,\tau+1}$ at time $\tau + \alpha$, it re Combines the received data and generates the encoded data $y_{i,\tau+\alpha+1}$ at time $\tau + \alpha + 1$, i.e.,

$$y_{i,\tau+\alpha+1} = \sum_{y_{j,\tau+\alpha} \in L_i} \bigoplus (c_{ji} \otimes y_{j,\tau+\alpha})$$  \hspace{1cm} (4)

$$= \sum_{y_{j,\tau+\alpha} \in L_i} \bigoplus \left( \sum_{h=1}^{N_H} \bigoplus (C_{hj,\tau+\alpha} \otimes x_{h,\tau}) \right)$$
where $\alpha > 0$, and $c_{ji}$ denotes the local coding coefficient for data from $v_j$ to $v_i$. In this paper, network coding is implemented based on RLNC $\Phi$ so that $c_{ji}$ is uniformly and randomly chosen from $GF$ with a size of $2^M$ ($GF(2^M)$), i.e., $c_{ji} \in GF(2^M)$. However, the proposed strategy is not limited to RLNC, and deterministic code designs $\Phi$ can be considered as well.

For a large-scale multi-hop wireless network, the process of recombining incoming packets in $\Phi$ can be performed significantly many times, which eventually allows the recombined packet to include all source data. Therefore, the terminal set of all packets in the network asymptotically converges to $T$ by making all packets identical. This is defined as packet anonymity of network coding, which is expressed in Proposition $\Box$.

**Proposition 1 (Packet Anonymity).** Network coding can asymptotically make both the information and terminal of each packet identical.

We next consider the impact of the packet anonymity on the node value. Let $\Phi$ be the network coding function in $\Phi$. Then, the node value function $\Gamma_{i,\tau}(v_j, T_h)$ in $\Gamma$ that is transformed by the network coding function $\Phi$ can be expressed as

$$
\Phi(\Gamma_{i,\tau}(v_j, T_h)) = \Phi(\Gamma_{i,\tau}(v_j), T_h) = f(\Gamma_{i,\tau}(v_j), T_h) = f(\delta_{i,\tau}(v_j), T_h).
$$

The equality between $\Phi$ and $\Phi$ is based on packet anonymity. $T$ in $\Phi$ is constant, so that the node value is only a function of $v_j$, which concludes $\Phi$. Therefore, we conclude that if the network coding function $\Phi$ is employed in intermediate nodes, multi-hop connections to terminals (i.e., $T_h$) need not be considered for node $v_i$. Rather, only the links directly associated with it should be considered as in a one-hop connection (i.e., $v_j$), leading to network decoupling described in Proposition $\Box$.

**Proposition 2 (Network Decoupling).** Network coding can decouple one-hop connections from the overall network formation.

Network decoupling can lead to the design of decentralized solutions by only considering node-environment interactions at each node, which are captured by the MDP framework introduced in Section $\Box$. The characteristics of network coding function $\Phi$ are shown in Fig. $\Box$

### 3.3 Source Reconstruction at Terminal Nodes

We next discuss the decoding process. Let $H_i = \{h | t \in T_h, \forall h \in H\}$ be an index set of source nodes for a terminal node $v_i$, and $p_1, \ldots, p_K \in L_i$ be the packets with the same

1. The time stamp for $c_{ji}$ is omitted because the local coding coefficient is used only for one time slot.

Fig. 2: Two characteristics of the network coding function $\Phi$. time stamp of source data that $v_i$ received. Then, we can construct a vector of network coded data $\tilde{y} = [\tilde{y}_1, \ldots, \tilde{y}_K]^T$ and the global coding coefficient matrix $C$ is expressed as

$$
C = \begin{bmatrix}
\tilde{C}_{11} & \cdots & \tilde{C}_{K1} \\
\vdots & \ddots & \vdots \\
\tilde{C}_{1K} & \cdots & \tilde{C}_{KK}
\end{bmatrix} = [\tilde{c}_1, \ldots, \tilde{c}_K]
$$

where $\tilde{c}_k = [\tilde{C}_{h1}, \ldots, \tilde{C}_{hK}]^T$ for $1 \leq h \leq N_H$.

Node $v_i$ is then able to perfectly reconstruct its source data, if $C$ satisfies the following two conditions: 1) $\tilde{c}_h \neq 0_K$ for all $h \in H_i$, where $0_K$ denotes all zero vector with length $K$, and 2) $C'$ is full-rank, where $C'$ is the matrix where all $\tilde{c}_h = 0_K$ for $1 \leq h \leq N_H$ are removed from $C$. Condition 1) ensures that the received packets include all data that should be reconstructed. This is a widely accepted condition under the wireless network settings because of the broadcasting nature of wireless communications. Condition 2) guarantees that the decoding process can uniquely reconstruct data $\tilde{x}_h$ for all $h \in H_i$. Because it is shown that RLNC makes the global coding coefficient matrix be full-rank with high probability, the condition 2) can be satisfied. The decoding process can then be implemented based on well-known approaches such as Gaussian elimination in a $GF$.

While the conditions for perfect reconstruction can generally be satisfied with high probability, some special applications (e.g., delay-sensitive applications, error-prone networks with a high packet loss rate, etc.) may cause a perfect reconstruction to fail. That is, random mixing in the assumption that the network coding may lead to an increased decoding delay if only a subset of the coded sources of interest arrives at the terminal node. In this case, alternative decoding algorithms can be deployed.

In the rest of this paper, we propose a distributed strategy for robust network formation.

### 4 MDP-Based Network Formation

In this section, we propose an MDP-based framework for network formation, where intermediate nodes $v_i, \forall i \in V$ of the network are considered as autonomous decision making agents to find the optimal strategy. An illustrative overview for the proposed framework is shown in Fig. $\Box$

2. It is shown in that if RLNC is employed, the probability that the global coding coefficient matrix is full-rank is at least $(1 - |D|/2^M)^{|E(G)|}$. In general settings, a GF size of $2^M$ is significantly larger than the number of terminals $|D|$ in the network. Hence, it is widely accepted that the global coding coefficient matrix is full-rank with high probability if RLNC is used.
Thus, $P(s'|s, a)$ means the probability that $s'$ effective nodes will be included in the transmission range of the node in the next time stamp by taking action $a$ from current $s$ effective nodes. Since the number of intermediate nodes in a bounded region follows an independent homogeneous PPP with node density $\lambda$, the state transition probability can be described as in Theorem 3.

**Theorem 3.** The state transition probability $P(s'|s, a)$ is given by

$$P(s'|s, a) = \begin{cases} 
\frac{(\lambda a)^{\xi'} \cdot e^{-\lambda a}}{\xi'} & a > 0 \\
1 & a = 0 \\
\frac{\xi'}{\xi' + 1} \cdot \left(1 - \frac{a}{\bar{a}_r}\right) & a < 0
\end{cases}$$

where $\xi \equiv \left[\frac{s}{1-\beta}\right]$ and $\xi' \equiv \left[\frac{s'}{1-\beta}\right]$.

**Proof.** Based on the Kolmogorov definition of conditional probability, the state transition probability given in (9) can be expressed as

$$P(s'|s, a) \cdot P(s) = P(s|s', -a) \cdot P(s').$$

Let $\xi$ be the number of nodes at time $\tau$ included in $\bar{a}_r$, and thus, the corresponding probability is given by

$$Pr\{\xi; \bar{a}_r\} = \frac{(\lambda \bar{a}_r)^\xi \cdot e^{-\lambda \bar{a}_r}}{\xi!}.$$

By considering the link failure rate $\beta$ of the channel, the expected number of effective nodes becomes $s = (1 - \beta) \cdot \xi$. Hence, $P(s) = Pr\{\xi; \bar{a}_r\}$ with integer value $\xi \equiv \left[\frac{s}{1-\beta}\right]$.

We assume that the state transition interval is short enough under mild regularity conditions [42]. Hence, $a = 0$ (which does not change the transmission range) does not lead to a state transition, i.e., $s' = s$. Therefore,

$$P(s'|s, a) \cdot P(s) = 1 \cdot P(s) = 1 \cdot P(s') = P(s|s', a) \cdot P(s').$$

If $a > 0$ (which enlarges the transmission range), more nodes can be included in the transmission region. Hence, $s' \geq s$. In this case, $P(s'|s, a) \cdot P(s')$ in (10) can be derived as

$$P(s'|s, a) \cdot P(s') = P(s'|s, a) \cdot Pr\{\xi; \bar{a}_r+\}$$

$$= \frac{(\lambda a)^{\xi'} \cdot e^{-\lambda a}}{(\xi' - \xi)!} \cdot \left(\frac{\xi'}{\xi'} \right)! 
\cdot \left(\lambda (\bar{a}_r+1)\right)^{\xi'} \cdot e^{-\lambda (\bar{a}_r+1)} 
\cdot \frac{\xi'}{\xi'}$$

$$= \frac{(\lambda (\bar{a}_r+1) - \bar{a}_r)\xi'}{\xi'} \cdot e^{-\lambda (\bar{a}_r+1-\bar{a}_r)} 
\cdot \left(\lambda (\bar{a}_r+1)\right)^{\xi'} \cdot e^{-\lambda (\bar{a}_r+1)} 
\cdot \frac{\xi'}{\xi'}$$

$$= \frac{(\lambda (\bar{a}_r+1)\xi')}{\xi'} \cdot e^{-\lambda (\bar{a}_r+1)} 
\cdot \left(1 - \frac{\bar{a}_r}{\bar{a}_r+1}\right)$$

$$= P(s|s', a) \cdot P(s').$$

Similarly, $P(s'|s, a) \cdot P(s) = P(s|s', a) \cdot P(s')$ in (10) is obtained for $a < 0$. 
Therefore, we conclude that the state transition probability can be expressed as \( \theta \).

Theorem 3 implies that the state transition probability is the probability that \( \xi' \) nodes are included in the transmission range \( a > 0 \). If \( a < 0 \), the probability that \( \xi' \) nodes are in \( a_{\tau+1} \) given \( \xi \) nodes in \( a_\tau \) is the probability that \( (\xi - \xi') \) nodes are included in \( |a| \).

### 4.0.4 Utility Function \( U(s, a, s') \)

We define the utility function of node \( v_i \) as a quasi-linear function that consists of a reward and a cost, i.e.,

\[
U(s, a, s') = u + \omega \cdot R(s, s') - (1 - \omega) \cdot a
\]

(12)

where \( R(s, s') \) is the reward function that represents immediate throughput improvement given the state transition from \( s \) to \( s' \) at the cost of taking action \( a \), which increases the transmission range. The cost intrinsically includes transmission power consumption at the node as well as the penalty for causing wireless inter-node interference. The weight \( \omega (0 \leq \omega \leq 1) \) can be used to balance the reward and the cost. For example, if \( \omega = 1 \), the cost associated with taking action \( a \) can be ignored, but only the throughput improvement is considered. Since a utility is generally non-negative, a constant \( u \) is introduced in (12), and it can be set such that \( U(s, a, s') \geq 0 \). The reward function \( R(s, s') \) is defined as

\[
R(s, s') = \gamma(s') - \gamma(s)
\]

where \( \gamma(s) \) denotes network throughput when the node is in state \( s \), which is a concave increasing function.

### 4.0.5 Discount Factor \( \rho \)

The discount factor \( \rho \in [0, 1] \) represents the degree of utility reduction over time, so that it determines the cumulative long-term utility. The discount factor can be determined based on the consistency of the network condition (e.g., \([43], [44]\)). For example, if the network condition is static, a large value of \( \rho \) can be used by imposing a high weight on the predicted future utilities whereas a lower value of \( \rho \) needs to be used in more dynamically changing network conditions.

Next, we show that the proposed framework satisfies the Markov property.

**Theorem 4.** The tuple \( (S, A, P(s'|s, a), U(s, a, s'), \rho) \) satisfies the Markov property.

**Proof.** Let \( (s_1, a_1), (s_2, a_2), \ldots, (s_\tau, a_\tau) \) be the sequence of events, where \( (s_\tau, a_\tau) \) is an event which includes an action at time \( \tau \) (i.e., \( a_\tau \)) and a corresponding resulting state (i.e., \( s_\tau \)). The initial transmission range and corresponding state are denoted by \( a_0 \) and \( s_1 \), respectively. To show that the tuple \( (S, A, P(s'|s, a), U(s, a, s'), \rho) \) satisfies the Markov property, our aim is to prove

\[ P(s_{\tau+1}|s_\tau, a_\tau) = P(s_{\tau+1}|s_\tau, a_\tau) \]

The state transition probability that action \( a_1 \) leads a node in state \( s_1 \) to a new state \( s_2 \) can be expressed as

\[ P(s_2|s_1, a_1) = Pr\{s_1 + (s_2 - s_1); \bar{a}_0 + a_1|s_1; \bar{a}_0 \} \]

3. In this proof, we add time stamps \( \tau \) on the notation of states and actions, e.g., \( s_\tau \) and \( a_\tau \), to clearly specify the time that an action is taken.

Fig. 4: An illustrative explanation of the proposed framework.

which implies that \( (s_2 - s_1) \) nodes are additionally included in the transmission range expanded by \( a_1 \). Similarly, \( P(s_3|s_2, a_2), (s_1, a_1) \) can be expressed as

\[
P(s_3|s_2, a_2, (s_1, a_1))
\]

\[
= Pr\{s_1 + (s_2 - s_1) + (s_3 - s_2); \bar{a}_0 + a_1 + a_2 | s_1 + (s_2 - s_1); \bar{a}_0 + a_1 \}
\]

\[
= Pr\{s_1 + \sum_{t=1}^{2} (s_{t+1} - s_t); \bar{a}_0 + \sum_{t=1}^{2} a_t | s_1 + \sum_{t=1}^{2} (s_{t+1} - s_t); \bar{a}_0 + \sum_{t=1}^{2} a_t \}
\]

\[
= Pr\{s_3 - s_2; a_2 = P(s_3|s_2, a_2).
\]

By induction, \( P(s_{\tau+1}|s_\tau, a_\tau), \ldots, (s_1, a_1) \) can be expressed as

\[
P(s_{\tau+1}|s_\tau, a_\tau) = Pr\{s_1 + \sum_{t=1}^{\tau} (s_{t+1} - s_t); \lambda(\bar{a}_0 + \sum_{t=1}^{\tau} a_t) | s_1 + \sum_{t=1}^{\tau} (s_{t+1} - s_t); \lambda(\bar{a}_0 + \sum_{t=1}^{\tau} a_t) \}
\]

(13)

\[
= Pr\{s_{\tau+1} - s_\tau; \lambda \cdot a_\tau \}
\]

(14)

The equality between (13) and (14) can be derived by

\[
s_{t+1} - s_t = \sum_{t=1}^{\tau} (s_{t+1} - s_t) - \sum_{t=1}^{\tau-1} (s_{t+1} - s_t)
\]

and

\[
\lambda \cdot a_\tau = \lambda(\bar{a}_0 + \sum_{t=1}^{\tau} a_t) - \lambda(\bar{a}_0 + \sum_{t=1}^{\tau-1} a_t)
\]

which completes the proof.

Theorem 4 shows that the proposed framework in this section can be modeled by the MDP. Fig. 4 shows an illustration of the proposed framework.

In the next section, we show how the strategy enables each node to make its own optimal decisions.
5 Distributed Network Formation Strategy

5.1 MDP-Based Optimal Strategy for Network Formation

The solution to an MDP is the optimal policy that maps the optimal actions performed in a particular state. Specifically, the policy is a function \( \pi : S \rightarrow A \) which returns an action for a state, i.e., \( \pi(s) = a \). The policy \( \pi \) is optimal if it can maximize the state-value function \( V(\pi) \).

The state-value function \( V_\tau(s) \) represents a cumulative utility at time \( \tau \), starting from state \( s \), as expressed where state \( s \) sequentially moves into \( s', s'' \), and \( s''' \). In \( V_\tau(s) \) includes the immediate utility \( U(s,a,s') \) and the discounted state-value of successive states \( \rho V_\tau(s') \). The expected value for the state-value function is thus expressed as

\[
E(V_{\tau+1}(s)) = \sum_{s' \in S} P(s'|s,a) (U(s,a,s') + \rho V_\tau(s'))
\]  

The optimal state-value function \( V^*(s) \) is the maximum state-value function over all policies, i.e,

\[
V^*(s) = \max_{\pi} E(V^\pi(s))
\]

where \( V^\pi(s) \) is the state-value achieved by the actions determined by policy \( \pi \) at every state. Finally, the optimal policy \( \pi^* \) is the policy that leads to \( V^*(s) \), and it is defined as

\[
\pi^* = \arg \max_{\pi} E(V^\pi(s)), \forall s \in S
\]

This is also known as the Bellman optimality equation \([45]\). Given the optimal policy \( \pi^* \), optimal action \( a^* \) for each state \( s \) can be determined such that

\[
a^* = \pi^*(s) = \arg \max_{a \in A} \sum_{s' \in S} P(s'|s,a) (U(s,a,s') + \rho V^*(s'))
\]

In practice, a near-optimal policy is widely used as it requires lower computational complexity. \( \pi^\epsilon \) is an \( \epsilon \)-optimal policy if

\[
||V^{\epsilon \pi}(s) - V^*(s)||_{\infty} \leq \epsilon
\]

which means that the error between \( V^{\epsilon \pi}(s) \), the state-value derived by \( \pi^\epsilon \), and \( V^*(s) \) is bounded by the optimality level \( \epsilon \). The \( \epsilon \)-optimal policy can be found using Algorithm 1.

Using stopping criteria, we show that Algorithm 1 converges to \( \epsilon \)-optimal policies in Theorem 5.

**Theorem 5.** The \( \epsilon \)-optimal policy can be achieved by Algorithm 1 if the iteration stops with condition

\[
||V_\tau(s) - V_{\tau-1}(s)||_{\infty} \leq \frac{1}{2\rho} \epsilon
\]

for all \( s \in S \).

**Proof.** See Appendix B

---

**Algorithm 1** Algorithm for \( \epsilon \)-Optimal Policy

**Require:** state space \( S \), action space \( A \), utility function \( U(s,a,s') \), weight \( \omega \), discount factor \( \rho \), state transition probability \( P(s'|s,a) \), optimality level \( \epsilon \)

1: **Initialize:** \( V_0(s) \leftarrow 0, \forall s \in S, \tau \leftarrow 0 \)
2: **while** \( V_\tau(s) - V_{\tau-1}(s) > \frac{1}{2\rho} \epsilon \) for any \( s \in S \) **do**
3:   **for** \( s \in S \) **do**
4:     **update** \( V_{\tau+1}(s) \leftarrow \max_a \sum_{s' \in S} P(s'|s,a) (U(s,a,s') + \rho V_\tau(s')) \)
5:   **end for**
6: **end while**
7: **return** \( \epsilon \)-optimal policies \( \pi^* \)

It can also be shown in Theorem 6 that Algorithm 1 converges to the optimal policy \( \pi^* \) by setting \( \epsilon = 0 \).

**Theorem 6.** The optimal policy \( \pi^* \) can always be achieved by setting \( \epsilon = 0 \) in Algorithm 1 i.e.,

\[
\lim_{\tau \to \infty} V_\tau(s) = V^*(s)
\]

for all \( s \in S \).

**Proof.** See Appendix C

The proof of Theorem 5 is shown in (59) in Appendix C. Based on this proof, we concluded that

\[
\lim_{\tau \to \infty} ||V_\tau(s) - V^*(s)||_{\infty} \leq \lim_{\tau \to \infty} \rho^\tau ||V_0(s) - V^*(s)||_{\infty}
\]

where \( |||| \) denotes the infinite norm. This shows that the convergence speed of Algorithm 1 significantly depends on the discount factor \( \rho \). Hence, the convergence speed can be controlled by discount factor \( \rho \).

Using the optimal policy, a node now can adaptively change its transmission range against network dynamics, which leads to a robust network. It is worth noting that the complexity to find the optimal policy at each node does not change, even if the total number of nodes in network increases. Hence, as the number of nodes increases, the total complexity to find the optimal policies of all nodes in the network increases linearly. This is because the proposed MDP framework of each node is not affected by individual network member nodes, instead it is only affected by node density \( \lambda \) in network. In the next section, we study how to determine the initial state for each node which determines the initial transmission range.

5.2 Stationary Network with Optimal Policy

Each node can periodically change its transmission range according to the optimal policy obtained from Algorithm 1. The resulting network can be in stationary, i.e., the number of network nodes is unchanged if each node takes action based on the optimal policy. In this section, we discuss how to initial conditions are determined such that the convergence speed for the optimal policy can be expedited in practice.

With the optimal policy \( \pi^* \), the proposed MDP framework is reduced to the Markov chain with a state transition
matrix $P$ whose element at $(s, s')$ is denoted by $P(s, s')$, which is expressed as

$$ P(s, s') = P(s'|s, \pi^*(s)) $$

This is the state transition probability $P(s'|s, a)$ in (9) with the optimal action $a = \pi^*(s)$. The state transition probability $P(s, s')$ provides the probability that a single state transition changes a node in $s$ to $s'$. Then, the limiting matrix $\lim_{n \to \infty} P^n$ and the limiting distribution $\sigma = [\sigma_1, \ldots, \sigma_s, \ldots, \sigma_{|S|}]$ which can be obtained as

$$ \sigma_s = \lim_{n \to \infty} \frac{\sum_{s' \in S} P^n(s', s)}{\sum_{s \in S} \sum_{s' \in S} P^n(s', s)} $$

where $\sigma_s$ denotes the probability of being in state $s$ after an infinite number of state transitions. Finally, the initial state $s^\dagger$ can be determined by choosing the state with the highest limiting distribution, i.e.,

$$ s^\dagger = \arg_{s \in S} \max \sigma_s $$

which allows the initial network to be formed close to the stationary network with the highest probability.

### 5.2.1 The optimal action includes no change of transmission range

If the optimal action at a state $s^*$ is not to change its transmission range, i.e., $a^* = \pi^*(s^*) = 0$, the $s^*$th row of $P$ can be expressed by the definition of $P(s'|s, a)$ in (9) as

$$ P(s^*, s') = \begin{cases} 1, & s' = s^* \\ 0, & s' \in \{S\setminus{s^*}\} \end{cases} $$

where $S \setminus{s^*}$ denotes the set of elements in $S$ excluding $s^*$. This allows the state transition matrix $P$ to be formulated in canonical form as

$$ P = \begin{pmatrix} Q & R \\ 0 & I \end{pmatrix} $$

where $Q \geq 0$ is a nonnegative matrix, $R > 0$ is a strictly positive matrix, $0$ denotes the matrix with zeros and $I$ denotes the identity matrix. The size of matrix $I$ becomes the number of states whose actions are zero.

Then, the limiting matrix of $P$ in (24) becomes

$$ \lim_{n \to \infty} P^n = \lim_{n \to \infty} \begin{pmatrix} Q^n & Q^{n-1}R + \cdots + QR + R \\ 0 & FR \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix} $$

where $F = (I - Q)^{-1}$ is the fundamental matrix of $Q$. $\lim_{n \to \infty} Q^n = 0$ as the element of $Q$ is in $[0, 1)$. Then, an element $\sigma_s$ in the limiting distribution $\sigma$ can be obtained based on (21)

$$ \sigma_s = \frac{\sum_{v \in S} (FR)_{ij}}{\zeta} $$

where $(FR)_{ij}$ denotes the $(i, j)$th element of the matrix $FR$ and $\zeta = \sum_{ij} (\sum_{v \in S} (FR)_{ij} + 1)$ is a constant. Therefore, the initial state $s^\dagger$ can be determined as

$$ s^\dagger = \arg_{s \in S} \max \sigma_s \\
= \arg_j \max \sum_{v \in S} (FR)_{ij}. $$

In the case where the set of optimal actions does not include no change in transmission range, the state transition matrix $P$ cannot be formulated as shown in (24). This is discussed next.

### 5.2.2 Optimal action includes change of transmission range

Since $a^* = \pi^*(s^*) = 0$ is not available as an action, the optimal actions are either to enlarge or reduce the transmission range.

If the optimal action at a state $s$ is to enlarge the transmission range (i.e., $a^* = \pi^*(s^*) > 0$), the $s^\ast$th row of $P$ becomes

$$ P(s, s') = \begin{cases} 0, & s' < s \\ \frac{\lambda_a}{(\xi - \bar{\zeta})}, & s' \geq s \end{cases} $$

Similarly, if the optimal action at a state $s$ is to reduce the transmission range (i.e., $a^* = \pi^*(s^*) < 0$), the $s^\ast$th row of $P$ becomes

$$ P(s, s') = \begin{cases} \frac{\lambda_a}{(\xi - \bar{\zeta})}, & s' \leq s \\ 0, & s' > s \end{cases} $$

The state transition matrix $P$ can be correspondingly expressed as a canonical form of

$$ P = \begin{pmatrix} U & Q_1 \\ Q_2 & L \end{pmatrix} $$

where $U$ and $L$ denote the upper and lower triangular matrices and $Q_1$ and $Q_2$ are strictly positive matrices. Since the optimal actions are determined by considering both rewards and costs, an optimal action can be determined to enlarge the current transmission range if a node is in a state with too few nodes. On the other hand, if a node is in a state with too many nodes, the optimal policy may determine the optimal action that reduces the transmission range such that the cost can be reduced. Hence, the state transition matrix $P$ in (29) consists of $(U, Q_1)$ and $(Q_2, L)$.

Note that $P^n$ for $n \geq 2$ is a strictly positive matrix. For example,

$$ P^2 = \begin{pmatrix} U & Q_1 \\ Q_2 & L \end{pmatrix} \begin{pmatrix} U & Q_1 \\ Q_2 & L \end{pmatrix} = \begin{pmatrix} U^2 + Q_1Q_2 & UQ_1 + Q_2L \\ Q_2U + LQ_2 & Q_2Q_1 + L^2 \end{pmatrix} $$

which becomes a strictly positive matrix. Hence, Perron-Frobenius theorem guarantees that there is a unique largest eigenvalue and the largest eigenvalue is 1 since $P$ is a stochastic matrix. Therefore, the unique limiting distribution $\sigma$ can be found as a row eigenvector of $P$ associated with eigenvalue 1, i.e., $\sigma P = \sigma$, and the initial state becomes the state with the largest limiting distribution as shown in (22).

The initialization phase of the proposed system can be expedited by choosing the initial state of each node that leads to the initial network.
6 SIMULATION RESULTS

In this simulation, we consider a wireless ad hoc network with multi-source multicast flows where multiple intermediate nodes aim to relay source data to multiple terminal nodes using network coding. All intermediate nodes are policy-compliant, meaning that each node builds its own optimal policy and correspondingly changes its transmission range based on the number of nodes included in its transmission range. In this section, we present a network formation result based on the proposed strategy, and then we show a performance comparison with other existing network formation strategies in applications with Wi-Fi Direct.

The proposed algorithms are designed and implemented by MATLAB and all the simulations are performed on a Windows 7 system configured by a Core i7 3.40GHz CPU with 8GB of RAM.

6.1 Numerical Results for the Proposed Strategy

We consider a network with two source nodes, two terminal nodes and multiple intermediate nodes. The number of intermediate nodes follows the PPP with a node density of 4/5. The network size denotes the size of the area in the network, and the different network sizes are considered. The results presented in this section are based on 1,000 independent experiments with a randomly generated number of nodes in a network size.

Fig. 5 shows the number of nodes in given network areas that are determined by the PPP with a node density of $\lambda = 4/5$. The line in the middle of each box in Fig. 5 denotes the median of the experiments, which are 29, 51, and 80 for network sizes of 36, 64, and 100, respectively. The top and bottom of each box are the 25th and 75th percentiles, respectively. Hence, it is confirmed that intermediate nodes are well generated by the PPP based on the node density.

Each agent builds $\epsilon$-optimal policy based on Algorithm 1 with the parameter $\epsilon = 0.01$, twenty states and five actions, i.e., $|S| = 20$ and $|A| = 5$. Fig. 5 shows the values of $V_\tau(s) - V_{\tau-1}(s)$ for all $s \in S$ over iterations and it is observed that $V_\tau(s) - V_{\tau-1}(s)$ approaches 0 as the number of iterations increases. Specifically, the iteration is terminated if $V_\tau(s) - V_{\tau-1}(s) \leq \frac{1}{2\tau^2} \epsilon_\tau$ and thus eventually $V_\tau(s) = V_{\tau-1}(s)$ with large enough iterations. Therefore, we conclude that the proposed algorithm converges. The convergence speed is dependent on the discount factor $\rho$ as shown in Fig. 6. For larger $\rho$, which takes into account longer future utilities, it takes a longer time (i.e., more iterations) to find $\epsilon$-policy. On the other hand, it takes less time to find the $\epsilon$-policy for a small $\rho$.

We next study the resulting network in terms of two connectivity measures: the number of constructed links and algebraic connectivity [47]. The number of links constructed in the network reflects the extrinsic connectivity and can be quantified by counting the number of links in the network. In contrast, the algebraic connectivity is the measure of intrinsic connectivity, i.e., how well the overall network is constructed. Fig. 6 shows the impact of weight $\omega$ in utility function (12) on network connectivity. Since $\omega$ is the weight of reward in the utility function, it is expected that the resulting networks are formed such that the rewards (or the cost) are given more weight than the cost (or the rewards) if $\omega$ is high (or low). In the simulations, we assume that there is no link failure in the channels (i.e., $\beta = 0$) and the discount factor is $\rho = 0.5$. Fig. 8(a) shows that the number of links is proportional to both network size

---

**Algorithm 2**: Algorithm for adaptation phase with packet transition

**Require**: optimal policy $\pi^*$

1. Initialize: $s \leftarrow s^\dagger$ // build a stationary network
2. while network is active do
3. // receive and combine packets
   store received packets in buffer
4. if $L_i \neq \emptyset$ then
5. // if the buffer is not empty
   build a network coded packet based on (4)
6. // update network topology
   check the current state $s$
7. find the optimal action: $a^* \leftarrow \pi^*(s)$
8. update the transmission range: $\bar{a}_{\tau+1} \leftarrow \bar{a}_\tau + a$
9. broadcast the network coded packet
10. $\tau \leftarrow \tau + 1$

![Fig. 5: The number of appeared nodes for given network size with a node density of $\lambda = 4/5$.](image)

![Fig. 6: Convergence process in Algorithm 1](image)
The Number of Iterations

The performance is measured by a path loss model, expressed as

\[ P_{TX} = P_{RX} \cdot \left( \frac{4\pi}{\lambda} \cdot \frac{d}{\alpha} \right) \]

where \( P_{TX}, P_{RX} \), \( \lambda \), and \( d \) denote transmission power, receive power, wave length, and the distance between transmitter and receiver, respectively.

In this simulation, we simultaneously consider three types of network dynamics: changes in member nodes of considered network, link failure rates, and node locations. To produce realistic dynamic network settings, the location of network nodes is changed in every time stamp, and the network member is updated, and the link failure rates \( \beta \) are updated (i.e., randomly selected in [0, 0.3]) every 5 time stamps. The simulation parameters are set to \( \omega = 0.53, u = 0.2, \epsilon = 0.01, |S| = 18 \) and \( |A| = 7 \).

We compare the performance of the proposed strategy with the following three existing network formation strategies.

1) Myopic: A myopic strategy is a special case of the proposed strategy with the setting of \( \rho = 0 \) in (18). The myopic solution does not consider the future utilities. Rather, it focuses on maximizing the immediate utility only, i.e.,

\[ \pi^{\text{myop}} = \arg \max_{a \in A} \sum_{s'} P(s'|s, a)U(s, a, s'), \forall s \in S. \]

2) Traskov [21]: A well-known centralized network formation strategy for network coding deployed networks. Traskov can provide a static network topology for a given node distribution by exploiting network coding opportunities. Hence, in the simulations, we consider the network where (network size \( \times \lambda \)) nodes are uniformly distributed, and we find the network topology based on Traskov. Since Traskov determines individual links, the transmission range of a node is assigned to include all links determined from Traskov. To ensure a fair comparison, the assigned transmission range is not changed over time since the computational complexity for Traskov is much higher than that of other distributed strategies.

3) TCLE [25]: A state-of-the-art distributed strategy for network formation based on a non-cooperative game. In this strategy, a node chooses its transmission power by balancing the target algebraic connectivity against transmission energy dissipation. To ensure a fair comparison, the same set of actions is employed as the

4) The travel time refers to the time taken for a data set to be transmitted across a network from source to terminal node. It includes processing delay, transmission delay, propagation delay and queuing delay.

### Table 2: Simulation Parameters

| Parameter          | Value | Parameter          | Value |
|--------------------|-------|--------------------|-------|
| \( \eta \)         | 1     | \( \alpha \)       | 0.5   |
| Channel Bandwidth  | 80 MHz| TX-RX Antennas     | 3×3   |
| Modulation Type    | 256-QAM| Coding Rate       | 5/6   |
| Guard Interval     | 400ns | PHY Data Rate      | 1300 Mbps |
| MAC Efficiency     | 70%   | Throughput         | 910 Mbps |
proposed strategy and the target algebraic connectivity of TCLE is set as 0.1, which is the average algebraic connectivity of the proposed strategy with $\omega = 0.53$. Note that the network topology determined by TCLE does not adaptively change.

To combat network dynamics, we allow TCLE to recalculate its solution every 5 time stamps. Note that in terms of computational complexity, these TCLE settings require higher complexity than the proposed and myopic strategies, where nodes simply lookup the optimal policies during all the simulations, which are obtained in the beginning of the simulations.

The average numerical results from 1,000 time stamps are summarized in Table 3 and illustrative results in the time stamp range of [380, 440] are shown in Fig. 10 and Fig. 11 for the radius of transmission range of a node and the number of total links in the overall network, respectively.

As shown in Table 3, the proposed strategy provides the highest system goodput as well as high successful connectivity ratio. The proposed strategy always outperforms the myopic strategy. This is because the policy of the myopic strategy focuses only on the immediate utility, while the proposed strategy considers not only the immediate utility but also future utilities. For example, time stamps in [430, 440] of Fig. 11 show that the proposed strategy more proactively responds to network dynamics than the myopic strategy by changing larger number of network links. Moreover, it is confirmed that the myopic strategy tends to result in smaller transmission ranges (shown in Fig. 10), which leads to a lower number of total active links in the network. Since small transmission range requires lower transmission power consumption, the myopic strategy consumes
The System Goodput and Power Consumption for different strategies are as follows:

| Strategy  | System Goodput [Mbps] | Successful Connectivity Ratio [%] | Power Consumption [dBm] |
|-----------|------------------------|-----------------------------------|-------------------------|
| Proposed  | 324.60                 | 75.65                             | 89.07                   |
| Myopic    | 276.51                 | 70.28                             | 80.17                   |
| Traskov   | 226.39                 | 38.19                             | 103.14                  |
| TCLE      | 317.36                 | 45.68                             | 76.22                   |

Fig. 11: The number of links in the resulting network in the presence of network dynamics.

lower power compared to the proposed strategy. However, in terms of power efficiency which can be computed as system goodput per unit power [Mbps/dBm] from Table 3, the proposed strategy has 3.644 which is higher than myopic strategy that is 3.449, leading to improved system goodput given power budgets.

While the second highest system goodput is achieved by the TCLE, it shows the second lowest successful connectivity ratio in Table 3. This implies that the TCLE can make successful connections between a source and a terminal based on significantly short paths. However, the TCLE is not an appropriate solution for applications that count on successful delivery over throughput. Rather, it is the most energy-efficient strategy (Table 3) as highlighted in [25], and it can determine smaller transmission ranges (in Fig. 10).

Traskov shows the lowest performance in terms of system goodput and successful connectivity ratio while it requires the highest power consumption. As shown in Fig. 10, Traskov does not change the transmission range once it is determined in the beginning of the simulation such that the result of network formation fails to overcome network dynamics.

7 CONCLUSIONS

In this paper, we focus on a distributed network formation strategy that can build a robust network against network dynamics. We show that network coding induces packet anonymity and network decoupling such that the MDP framework can be employed at each intermediate node. The intermediate nodes determine an optimal policy based on MDP, and the policy allows the nodes to determine optimal transmission ranges that maximize the long-term cumulative utilities. The optimal transmission ranges are determined by explicitly considering current network conditions and future network dynamics. We further show that the resulting network of the proposed strategy converges to the stationary networks, and we propose how to determine an initial network that can rapidly converge to the stationary network. Simulation results confirm that the resulting network of the proposed strategy can adaptively change by responding to network dynamics such as unstable channel condition with high link failure rate, node mobility, and corresponding changes in member nodes associated with the considered network.

Proof. We define
\[
(T^* V_\tau)(s) = \max_{a \in A} \left( \sum_{s' \in S} P(s'|s,a) \left( U(s,a,s') + \rho V_\tau(s') \right) \right).
\] (30)
This updates the state-value function with the action that provides the maximum expected long-term state value.

Appendix A
Bellman Operation and its Properties
Let \( T^* \) be the Bellman optimality operator [15] for \( V_\tau(s) \), which maps a foresighted state-value function to a foresighted state-value function (i.e., \( T^* : \mathbb{R}^{|S|} \rightarrow \mathbb{R}^{|S|} \)), defined as,
\[
(T^* V_\tau)(s) = \max_{a \in A} \left( \sum_{s' \in S} P(s'|s,a) \left( U(s,a,s') + \rho V_\tau(s') \right) \right).
\] (30)

The inequality between (31) and (32) is satisfied because \( T^* \) is monotonic and \( \rho \)-contractive, as shown below.

Proof. (Monotonicity of Bellman Optimality Operator) \( V_\tau(s) \leq V'_\tau(s), \forall s \Rightarrow (T^* V_\tau)(s) \leq (T^* V'_\tau)(s) \)
\[
\begin{align*}
(T^* V_\tau)(s) - (T^* V'_\tau)(s) &= \left( \sum_{s' \in S} P(s'|s,a^*) \left( U(s,a^*,s') + \rho V_\tau(s') \right) \right) \\
&\geq \left( \sum_{s' \in S} P(s'|s,a^*) \left( U(s,a^*,s') + \rho V'_\tau(s') \right) \right) \\
&= \rho \sum_{s' \in S} P(s'|s,a^*) (V_\tau(s') - V'_\tau(s')) \\
&\leq 0
\end{align*}
\] (31) (32)
The inequality between (31) and (32) is satisfied because \( 0 < \rho < 1, P(s'|s,a^*) \geq 0 \), and \( V_\tau(s') - V'_\tau(s') \leq 0 \). Therefore, if \( V_\tau(s) \leq V'_\tau(s) \), then \( (T^* V_\tau)(s) \leq (T^* V'_\tau)(s) \). \( \square \)

Proof. (Additivity of Bellman Optimality Operator) \( (T^* V_\tau + d)(s) = (T^* V_\tau)(s) + \rho d, \forall s \in S \)
\[
\begin{align*}
(T^* V_\tau + d)(s) &= \max_{a \in A} \left( \sum_{s' \in S} P(s'|s,a) \left( U(s,a,s') + \rho (V_\tau(s') + d) \right) \right) \\
&= \max_{a \in A} \left( \sum_{s' \in S} P(s'|s,a) \left( U(s,a,s') + \rho V_\tau(s') \right) \right) + \rho d \sum_{s' \in S} P(s'|s,a) \\
&= (T^* V_\tau)(s) + \rho d
\end{align*}
\] (33) (34)
where \( \sum_{s' \in S} P(s'|s,a) = 1 \) in (34). Therefore, \( (T^* V_\tau + d)(s) = (T^* V_\tau)(s) + \rho d, \forall s \in S \). \( \square \)

Proof. (\( \rho \)-Contractive Property of Bellman Optimality Operator) \( \| T^* V_\tau(s) - T^* V'_\tau(s) \|_\infty \leq \rho \| V_\tau(s) - V'_\tau(s) \|_\infty, \forall s \in S \)

Proof. We define \( d \) as,
\[
d = ||V_\tau(s) - V'_\tau(s)||_\infty,
\] (35)
where \(\|\cdot\|_{\infty}\) denotes the infinite norm, defined as
\[
\|V_\tau(s)\|_{\infty} = \sup \{|V_\tau(s)| : s \in S\}.
\]

Then the following equations can be obtained from (35).
\[
\begin{align*}
V_\tau(s) - d &\leq V'_\tau(s) \leq V_\tau(s) + d \\
T^*(V_\tau(s) - d) &\leq (T^*V'_\tau)(s) \leq T^*(V_\tau(s) + d) \\
T^*V_\tau(s) - \rho d &\leq (T^*V'_\tau)(s) \leq T^*V_\tau(s) + \rho d \\
\|T^*V_\tau(s) - T^*V'_\tau(s)\|_{\infty} &\leq \rho d
\end{align*}
\]

The Bellman optimality operator is used between (37) and (38), and Property 8 is used between (38) and (39). By substituting \(d\) in (40) for (35), we conclude the following equation.
\[
\|T^*V_\tau(s) - T^*V'_\tau(s)\|_{\infty} \leq \rho\|V_\tau(s) - V'_\tau(s)\|_{\infty}
\]

\(\Box\)

**APPENDIX B**

**PROOF OF THEOREM 5**

In this proof, we show that for all \(s \in S\),
\[
\|V_\tau(s) - V_{\tau-1}(s)\|_{\infty} \leq \frac{1 - \rho}{2\rho} \epsilon \Rightarrow \|V^{*\epsilon}(s) - V^*(s)\|_{\infty} < \epsilon.
\]

By using the definition of infinite norm, \(\|V^{*\epsilon}(s) - V^*(s)\|_{\infty}\) can be written as follow.
\[
\begin{align*}
\|V^{*\epsilon}(s) - V^*(s)\|_{\infty} &\leq \|V^{*\epsilon}(s) - V_{\tau}(s)\|_{\infty} + \|V_{\tau}(s) - V^*(s)\|_{\infty} \\
&\leq \|V^{*\epsilon}(s) - V_{\tau}(s)\|_{\infty} + \|V_{\tau}(s) - V_{\tau-1}(s)\|_{\infty} + \|V_{\tau-1}(s) - V^*(s)\|_{\infty} \\
&\leq \rho\|V^{*\epsilon}(s) - V_{\tau}(s)\|_{\infty} + \rho\|V_{\tau}(s) - V_{\tau-1}(s)\|_{\infty} + \rho\|V_{\tau-1}(s) - V^*(s)\|_{\infty}
\end{align*}
\]

We now bound each part of the summation in (43) individually:
\[
\begin{align*}
\|V^{*\epsilon}(s) - V_{\tau}(s)\|_{\infty} &\leq \|T^{*\epsilon}V^{*\epsilon}(s) - V_{\tau}(s)\|_{\infty} \\
&\leq \|T^*V^{*\epsilon}(s) - T^*V_{\tau}(s)\|_{\infty} + \|T^*V_{\tau}(s) - V_{\tau}(s)\|_{\infty} \\
&\leq \rho\|V^{*\epsilon}(s) - V_{\tau}(s)\|_{\infty} + \rho\|V_{\tau}(s) - V_{\tau-1}(s)\|_{\infty}
\end{align*}
\]

where \(T^{*\epsilon}\) denotes the Bellman \(\epsilon\)-optimality operation and it satisfies \(V^{*\epsilon}(s) = T^{*\epsilon}V^{*\epsilon}(s)\) because \(V^{*\epsilon}(s)\) is the fixed point of \(T^{*\epsilon}\), which is used in (45). The inequality between (45) and (46) is obtained by using the definition of infinite norm. Since \(\pi^{*\epsilon}\) is maximized over the actions using \(V_\tau(s)\) in (47), this implies that \(T^{*\epsilon}V_{\tau}(s) = T^*V_{\tau}(s)\). The inequality between (47) and (48) is based on Property 9.

Similarly, the second part of the summation in (43) becomes
\[
\begin{align*}
\|V_{\tau}(s) - V^*(s)\|_{\infty} &\leq \|V_{\tau}(s) - T^*V_{\tau}(s)\|_{\infty} + \|T^*V_{\tau}(s) - V^*(s)\|_{\infty} \\
&\leq \rho\|V_{\tau}(s) - V_{\tau}(s)\|_{\infty} + \|V_{\tau}(s) - V^*(s)\|_{\infty} \\
&\leq \rho\|V_{\tau}(s) - V_{\tau-1}(s)\|_{\infty} + \|V_{\tau}(s) - V_{\tau}(s)\|_{\infty} + \rho\|V_{\tau}(s) - V^*(s)\|_{\infty}
\end{align*}
\]

By substituting (48) and (50) in (43) and using the condition \(\|V_{\tau} - V_{\tau-1}\|_{\infty} \leq \frac{1 - \rho}{2\rho} \epsilon\) in (41), we conclude the following.
\[
\|V^{*\epsilon}(s) - V^*(s)\|_{\infty} \leq \frac{2\rho}{1 - \rho}\|V_\tau(s) - V_{\tau-1}(s)\|_{\infty} \leq \frac{2\rho}{1 - \rho}\left(\frac{1 - \rho}{2\rho}\epsilon\right) = \epsilon
\]

Therefore, for all \(s \in S\), (41) is satisfied.
APPENDIX C
PROOF OF THEOREM 6

In this proof, we show that Algorithm 1 converges to the optimal policies $\pi^*$ by showing that the infinite interactions of the Bellman optimality operation converge to the optimal state-value function $V^*(s)$, such as

$$\lim_{\tau \to \infty} V_\tau(s) = V^*(s), \forall s \in S.$$  (51)

This is identical to the following equation based on the definition of the infinite norm in (36).

$$\lim_{\tau \to \infty} ||V_\tau(s) - V^*(s)||_\infty = 0, \forall s \in S$$  (52)

Hence, in this proof, we prove (52) as below.

$$\lim_{\tau \to \infty} ||V_\tau(s) - V^*(s)||_\infty = \lim_{\tau \to \infty} ||T^*V_{\tau-1}(s) - T^*V^*(s)||_\infty$$  (53)

$$\leq \lim_{\tau \to \infty} \rho||V_{\tau-2}(s) - V^*(s)||_\infty$$  (54)

$$\leq \cdots \leq \lim_{\tau \to \infty} \rho^\tau||V_0(s) - V^*(s)||_\infty$$  (55)

$$= 0$$  (56)

Based on the definition of $V^*(s)$ in (17), $V^*(s) = T^*V^*(s)$ is used in (54), and the inequality between (54) and (55) is based on Property 2. Since $0 < \rho < 1$, $\lim_{\rho \to \infty} \rho^\tau = 0$ in (56). Therefore, $\lim_{\tau \to \infty} ||V_\tau(s) - V^*(s)||_\infty = 0, \forall s \in S$ so that $\lim_{\tau \to \infty} V_\tau(s) = V^*(s), \forall s_i, \tau \in S.$
